THE JOURNAL

OF THE

/// Society of Chemical Industry.

VOL. V.—1886.

390766
1.4.41

MANCHESTER :

EMMOTT AND COMPANY, NEW BRIDGE STREET, STRANGWAYS.

Journal of the Society of Chemical Industry.

INDEX OF VOL. V.—1886.

INDEX OF AUTHORS' NAMES.

	PAGE		PAGE
Abbe, Glass for Standard Thermometers.....	157	Arnold, C. Nitrogen Determination	617
Refractometer	157	Arth, G. Menthol Derivatives	436
Abbott, Explosives	592	Aryine, F. W. Testing Lubricants	123
Vulcanised Indiarubber	610	Asboth, Nitrogen Determination	510
Abel, C. D. Lanolin	672	Ashman, T. N. Treatment of Leather	609
Saponification	381	Ashwell, J. R. Antimony Mordant	301
Abel, Sir F. A. Carbon in Iron and Steel	493	Dyed Hosiery and Irritation of the Skin	236
Treatment of Sewage	319	Ashwell, J. H. Utilisation of Soap Suds	102
Panelastite	199	Atkinson, A. J. Estimation of Sulphur in Coal	154
Abel, Sir F. A., and Redwood B. Mineral Oil Lamps	169	Atkinson, R. W. Discussion on Alum Manufacture	22
Abel, W. F. Discussion on Filtration of Water	226	Estimation of Manganese	365
Abel and Field. Impurities in Commercial Copper	85	Japanese Method of Making White Lead	312
Abell, W. F. See Fletcher and Abell	91	Voluimetric Test for Manganese	122, 167
Actien-Gesellschaft für Anilin-Fabrikation, Berlin. Mixed Azo-colours	595	Attwood, G. Treatment of Ores	167
Adair-Roberts, F. G. See Roake	435	Anbery, J. M. See Clute	609
Adams. Determination of Butter in Milk	498	Audoynaud, A. Adulteration of Olive Oil	168
Adie. Testing Cement	197	Audoynaud, A., and Zacharewicz, E. Stable Manure	541
Aducoo, V., and Mosso, H. Saccharine as an Antiseptic	616	Austin, F. J. Disinfectors	26
Ainsworth, R. H., and Manby, E. B. Bleaching and Dyeing (illus.)	661	Anwers, H. Derivatives of Pseudo-cumol	326
Ainsworth, R. H., and Manby, S. B. Scouring and Washing Machine	609	Axenfeld, D. Reaction for Aluminium	35
Aitken, Deposition of Soot	571	Ayrton, M. Purifying Oil	510
Aitken, H. Preventing Scale in Boilers	91	Backelandt, L. Separating Columbin and Copper	471
Treatment of Ores	426	Baker, W. Coke and Tar as Fuel for Gas-producers	471
Alavoine, F. A. M. Hydraulic Mains for Gas	317	<i>Badische Anilin u. Soda Fabrik.</i> Colours from Dioxystar-taric Acid	127
Albert, H. Basic Slag as Manure	465	Baeyer and Drewsen. Indigo Derivative	320
Albert, H. and E. Potassium Phosphate as Manure	672	Baeyer and Eiehlhorn. Substance resembling Dextrin, from Lupin Seeds	385
Alexander, J. O. Relative Quantities of Sucrose and Glucose in Sugar Cane	117	Baeyer and Hemilian. Condensation Products of Secondary Aromatic Alcohols	321
Alexander, T. and S., and Paterson, R. Oil Gas	169	Baeyer and Jackson. Ethylquinoline	161
Alexander, N. A., and Ivass, L. Tanning Hides	433	Baeyer and Schiff. Pyridine	236
Allan, E. C. Filters (illus.)	521	Bagnall, J. Dissolving Indiarubber	165
Allan, E. C., and F. M. Acetic Acid Manufacture (illus.)	31	Bailey, C. J. C. Filter	415
Allen, A. H. Chemistry of Fixed Oils	65	Bailey, C. J. C., and Dean, S. C. Utilising Waste Heat of Furnaces	421
Discussion on Materials used in Dyeing	71	Bailey, W. H. Discussion on British Chemical Industries	357
Examination of Fixed Oils	282	Fusible Plugs	233
Examination of Oils	303, 191	Bailey. Discussion on Calorimeter	581
Viscometer	127	Bailly, P. Electrodes for Batteries	676
Allen, W. Acid Taps and Valves	368	Baird, F. Peat Fibre	172
Alliott, J. B. Filter Presses	169	Baker, H. M. Resorcin Blue	662
Allison, H. J. Secondary Batteries	217	Balbani. Destruction of Ova of Phylloxera	466
Amber, A. J. Employment of Hydrocarbons as Fuel	373	Balfour, J. L., and Lane, J. Gas Manufacture	522
Ambuhl and Elsner. Detection of Artificial Colour in Claret	519	Ball, C. J. Combined Gas and Vapour Force Generator	316
Amthor, C. Analysis of Alsatian Wine	497	Balkand. Alkaloids in Old Flour	171
Andersen, C. P. Hematein	609	Bread	171
Anderson. The Air of Dwellings and Schools	513	Ballard, E. G. Methyl Orange as an Indicator	287
Sulphur in Coal Gas	281	Balling, C. A. M. Antimony Production in Banya	671
Anderson, A. W. White Lead	325	Production of Antimony in Blast Furnaces	328
Anderson, G. Discussion on Utilisation of Tar	563	Balls, M. See Fromm, A.	211
André. See Berthelot	511	Balmann. Potassium Chlorate	498
Andreal, B. Gas Generator	222	Bamberger. Reactions for Orthodiketones	589
Andresen, M. Safranin and Methylene Blue	508	Bamberger, E., and Calman, A. Mixed Azo-compounds	26
Andrews. Calorimeter	382	Bamberger, E., and Philip, M. Pyrene	419, 585
Andrews, A. See Hitchingman, E. L.	195	Banister. Sucrose in Cereals	36
Andrews, C. W. See Norton	373	Bannehr, J. Treatment of Sewage	675
Angell, A. Purification of Sewage	38	Banner, S. Turpentine Substitute	522
Anschütz. Malic Acid	216	Baptiste-Régi, J., and Folie-Desjardins, C. Bisulphide of Carbon	167
Archbutt. Standard of Viscosity	131	Barbe, F. Phosphoric Acid Manure	104
Archbutt, L. Analysis of Oils	303	Barbe, M. C. P. Refined Sugar	453
Archib, J. A. See Ford, A.	671	Barbot. Examination of Oils	305
Archer, J. B. Gas from Hydrocarbons	418	Barnes, J. Gasometric Assaying (illus.)	115
Water Gas	171	Barraclough, W. Examination of Oils	283
Arducco and Mosso. Physiological Action of Saccharine	421	Barringer, R., Wallis, J. H., and Barringer, W. Laundry Blue	523
Armack, J. F. O. See Meyn	693	Barry, J. H. Treatment of Sewage Sludge	675
Armour, L. H. Writing Ink	30	Bassett. Hexachlorobenzene	232
Armstrong, H. E. Discussion on Utilisation of Tar	563	Bauer. See Classen and Bauer	39
Action of Steam on Carbonic Oxide	379	See Classen	334
Russian Turpentine	7	Bauer, H. See Stadel, W.	596
Treatment of Sulpho-acids with Steam	317	Bauer, M. Extraction of Fat	132
Discussion on Koch's Water Test	120	Hauschinger. Cements	189
Armstrong, H. E., and Miller, A. K. Hydrocarbons at High Temperatures	374	Bayer. Estimation of Alumina	550
Hydrolisation of Sulpho-acids	95	German Chemical Industries	351
Armstrong, J. T. Electrical Batteries	615, 616		

	PAGE		PAGE
Bayer and Co. See <i>Farbenfabriken</i>	427, 428	Blarez, C. Detection of Acid Magenta.....	518
Bayer, F., and Co. Methyl-violet.....	320	Blum, L. Application of the "Thomas" Slag.....	583
Bayer, K. J. Determination of Alumina.....	11	Determination of Silicon in Iron.....	502
Bayley, Estimation of Copper.....	51	Value of "Thomas" Slag as Manure.....	101
Solubility of Nitric Oxide.....	83	Blumenthal, M. Ferments.....	105
Bayley, T. Oxide of Iron.....	210	Blundstone, E. R. Utilisation of Waste Tin.....	558
Beatson, W. Recovery of Tin from Scrap.....	493	Boake, A., and Roberts, F. G. A. New Sulphite for	
Bechaux, L. Rectification of Alcohol.....	613	Brewing.....	170
Beck, P. See Will, W.....	456	Boake, A., and Roberts, F. Sulphites of Potash.....	435
Becke, M. Influence of Lime in Wool-dyeing.....	530	Boake, A., and Adair-Roberts, F. G. Disintegrants.....	161
Becker, E. Chemical Balances.....	219	Boas-Boasson, J. Oxidation of Thio-Bases of Diamines.....	672
Becker, F. Gunpowder.....	157	Brownnicki, A. Treatment of Phosphatic Slag.....	672
Beckett, Cupola with Steam Blast.....	451	Bodlander, G. Analysis of Peptone.....	617
Beckett, G. H. See Machab, W.....	267	Bodenbender, Determination of Invert Sugar.....	613
Beckles, S. H. See Punshon and Beckles.....	55	Boehm, See Rithausen und Boehm.....	243
Beckurts, H. Brucine.....	616	Boetsch, Antimony Oxalate as Mordant.....	163
Determination of Phenol.....	516, 517	Bohme, Influence of Frost on Cement.....	492
Hydrochloric Acid free from Arsenic.....	531	Strength of Cement.....	196
Permanganate as Reagent for Alkaloids.....	510	Boillot, Sterilisation of Bacteria.....	262
Bedson, P. P. Address to Newcastle Section.....	581	Bullon, Sir F. Caustic Soda Manufacture.....	91
Discussion on Magnesium Sulphate.....	585	Bolm, W. See Sweetser.....	608
Behr and Dorp. Synthesis of Anthracene.....	321	Bompas, G. G. Ship-sheathing Metal.....	85
Behrens, E. A. Bleaching Resins.....	532	Bonne, C. R. Testing Brewing Materials.....	512
Behrus, G. Filters.....	308	Borles, L. See Marchal.....	384
Belby, Discussion on Specific Heats of Gases.....	11	Borland, W. D. Granulated Antiseptics.....	219
Pyrometer.....	635	Bornstein, E., and Herzfeld, A. Oxidation of Levulose.....	197
Bein, S. Estimation of Zinc.....	519	Borstrager, A. Determination of Tartaric Acid in Lees.....	510
Belani, L. Value of Charcoal and Coke in Blast Fur-		Witt's Filtering Apparatus.....	510
naces.....	167	Borodin, Asparagin in Plants.....	385
Belcher, J. C. Determination of Glycerine.....	70	Bosse, H. Cement from Furnace Slags.....	211
Bell, Discussion on Chloride of Sulphur.....	611	Bosshard, E. See Schulze, E.....	173, 385
Bell, A. Filters.....	141	Batsch, C. Antimony Oxalate.....	293
Bell, A. J. Filters.....	105	Bottger, Hydrated Sodium Sulphides.....	531
Bell, D. W. See Sweetser.....	608	Bottlinger, Action of Benzyl Chloride on Aromatic	
Bell, J. Densities of Fats.....	66	Hydrocarbons.....	221
Separation of Alumina from Phosphates.....	152	Bouchardat, G., and Lafont, J. Oxidation of Oil of Tur-	
Bell, J. C. Density of Butter.....	66	pentine.....	174
Bellingrodt, F. Extraction of Mercury from Zinc-blende	531	Boudet, Elaidin Test for Olive Oil.....	305
Benardos, N. de, and Olaszewski, S. Use of Voltaic Arc in		Bouillon, E. "Dry Extract" in Wines.....	612
Working Metals.....	675	Bouillet, L. J. B. Ultramarine.....	523
Bender, C. F. Aquinite.....	320	Bouile, L. Saving Hops in Brewing.....	453
Benedikt, See Zsigmondy.....	177	Treatment of Hops.....	515
Benedikt and Zsigmondy. Determination of Glycerine.....	70	Boulton, W. Decoration of Glass.....	100
Benjamin, P. Secondary Batteries.....	106	Bousingault, Iron in Daily Food.....	227
Benkiser, See Nietzki.....	450	Bousingault, Stable Manure.....	511
Bennet, W. G. B. Treatment of Sewage.....	39	Bowers, J. A. Purifying Water.....	158
Bennet, O. W. Carburetter for Air, etc.....	373	Bowkley, W. South Staffordshire Coal.....	414
Bennett, A. R. Voltaic Batteries.....	172	Box, T. Strength of Cast Iron.....	292
Bennett, R., and Peet, H. Composition for Mural Decora-		Braun, T. Tannin.....	672
tion.....	103	Brandstätter, J. Artificial Stone.....	327
Bensemann, R. Estimation of Glycerol in Wine.....	509	Brandt, Burner for Petroleum Residues (illus.).....	474
Bente, T. Treatment of Lupines.....	169	Brenner, W. Treatment of Sewage.....	451
Berensford, Lord C. Rivers Purification Bill.....	158	Brentini, P. Saponaceous Material.....	381
Berges, A. von. Krupp's Pyrometer (illus.).....	23	Brevort, H. L., and Roberts, J. L. Electric Batteries.....	106
Berglund, E. Bromine in Sea Water.....	40	Brin, A. Binoxide of Barium.....	428
Bergstrom, Bessemer Steel.....	607	See Quentin and Brin.....	101
Berger, Manuring Experiments with Phosphates.....	541	Brin, L. Q. and A. Separation of Oxygen and Nitrogen	
Berlin <i>Anhaltische Maschinenbau-Aktion Gesellschaft</i> ,.....		from Air.....	40
Treatment of Ammoniacal Liquors.....	167	Brin, Q. and A. Oxide of Barium.....	31
Berliner, T. Extraction of Fat from Bones.....	672	Brinell, J. A. Change of Texture of Steel.....	538
Bernays, Discussion on Testing Cement.....	199	Brock, J., and Rowell, W. A. Chromates.....	211
Bernbeck, Decomposition of Apomorphine Hydrochloride.....	173	Brock, J., and Saye, E. Conveying and Distributing Acid,	
Bernthsen, A. Action of Heat on Aniline.....	317	etc. (illus.).....	427
Incandescent Lamps.....	511	Brookes, A. G. Acid for Beverages.....	616
Phenazine.....	661	Distillation of Glycerine.....	329
Berrington, A. T. D. Regenerating Waste Gases.....	160	Manufacture of Glycerine.....	431
Berry, E. E. See Sulman.....	177	Metallic Alloys.....	31
Bert, P. Sterilisation of Bacteria.....	262	Brown, Solid Caustic Soda.....	283
Berthelot, Carbon Chloride.....	232	Brown, E. O. Iodide Process of Valuation of Copper Ores.....	49
Fixation of Nitrogen by Soils.....	103	Brown, J. Campbell. Discussion on Cotton-seed Oil.....	205
Berthelot and Vieille. Rate of Explosion of Hydrogen		Address to Liverpool Section.....	565
and Oxygen.....	370	Discussion on Redonda Phosphate.....	572
Influence of Dilution on Explosion of Gases.....	15	Discussion on Wood as a Paper-making Material.....	350
Heat of Combustion.....	159	Saccharine.....	319
Berthelot and Andre. Formation of Oxalic Acid in Plants.....	511	Brown, L. Pigments from Iron Ore.....	35
Berthier, Caloric Value of Fuel.....	581	Brucke, Pepsin.....	451
Berzelius, Etching on Glass.....	669	Bruhns and Volpert, Invert Sugar.....	428
Beurl, J. M. Manufacture of Glass Articles.....	536	Brunjes, F. Carbonate of Potash.....	428
Bevan, See Cross and Bevan.....	239	Brunner, Discussion on Redonda Phosphate.....	571
Bevan, E. J. See Menzies, R. C.....	321, 332	Brunner, Mond and Co. Soda.....	356

Beyer, C. Action of Acetone on Aniline.....	238	Bryant, J. H. See Thompson and Bryant.....	100
Bichel, C. E. Explosives.....	457	Buch, See Zega.....	509
Biedermann, A. Hydroxythionaphthen.....	418, 419	Buchner, E., and Curtius, T. Gelatin.....	381
Thiophenol.....	419, 481	Buchner, G. Mercurous Sulphate.....	199
Biel, T. Reaction of Cocaine.....	335	Buckingham, A. Substitute for Leather.....	495
Biel, H., jun. Experiments with "Thomas" Slag.....	212	Budd, J. Imitation Marble, Malachite, etc.....	327
Bigazzi, Invert Sugar.....	517	Buff, Black-ash Vat.....	358
Bindscheller, Green Dye.....	508	Buisite, A. Composition of Wool-grease.....	539
Birch, W. Washing and Dyeing Machine (illus.).....	239	Bunn, P. C. Pigments from Waste Lead Ores.....	432
Birnbaum, Acids in Butter.....	618	Bunsen, Pressure of Explosion.....	12
Bischoff, G. Volumetric Estimation of Chlorine.....	286	Bonte, H. Valuation of Gas-coal.....	653
Bischof, G. Analyses of Fire-Clay.....	459	Burjorji, A. Thermo-electric Batteries.....	615
Bischof, G. Notes on Koch's Water Test (illus.).....	111	Barre, Estimation of Copper.....	51
Bischof, Action of Spongy Iron on Liquors containing		Butler, S. Artificial Fuel.....	317, 373
Arsenic.....	300		
Discussion on Treatment of Sewage.....	318	Cahn, E. L. Methylanthragalol.....	509
Organisms in Water.....	267	Caldewood, Standard of Viscosity.....	131
Black, W. Artificial Fuel.....	256	Calman, A. See Rumberger and Calman.....	26
Blades, F. J. See Dixon.....	168	Calvert and Johnson. Action of Acids on Copper.....	85
Blake, Discussion on Filtration of Water.....	226	Candy, F. Carbonised Materials for Filters.....	675
Blarez, C. Determination of Sulphurous Acid.....	517	Carbonaceous Clay.....	671
Reactions of Sulphoated Magentas.....	178	Canning, Ammonia-soda Process.....	322

	PAGE		PAGE
Cannizzaro, S. Santonin.....	49	Coleman, J. B. Discussion on Filtration of Water	226
Cantani, A. Inhalation of Bacteria	116	Coleman, J. J. Production of Cold	139
Carey, A. E., and Latham, E. Mortar Machine	160	Purification of River Water (illus.)	650
Carnelley, A. Action of Water on Copper	87	Viscosity Tests for Oils (illus.)	339
The Air of Dwellings and Schools	513	Collin, Safranin	319
Carbon Monochloride	232	Collinge, T. Carburetting Air	5
Carnelley, T., and Schleselman, J. Amidodiphenylsulphonic Acid	376	Collins, C., and Co. Antiseptic	451
Caro, S. Solubility of Calcium Carbonate	321	Collins, W. Ship-seathing Metal	85
Carpenter, R. F. Methyl-orange as an Indicator	287	Colson, A., and Gautier, H. Process of Chlorination	321
Solubility of Silver Chromate	286	Coltart, M. G., and Menzies, J. Oils for Batching Wool	323
Carpenter, S. M. Toughened Cast Iron	294	Condy, H. B. Alkaline Sulphates and Hypsulphates	321
Carr, G. W., and Dickinson, J. Composition for Ships' Bottoms	193	Conrad, M., and Guthzeit, M. Action of Dilute Acids on Galactose and Arabinose	36
Carré, Ice Machine	137	Action of Dilute Acids on Dextrose and Levulose	613
Carter, J. W. See Lathrop and Others	217	Decomposition of Milk-sugar by Hydrochloric Acid	672
Casimajor, Filter	510	Cook, W. Scouring Wool	46
Case, W. E. Electric Battery worked by Hent	436	Cooke, G. K. Designs on Coloured Glass	19
Cassell, H. R. Treatment of Metals by Electrolysis	151	Cooper, A. J. Detection of Metals in Water	81
Castelaz, C. Mercury Fumate	218	Cooper, H. J. Portland Cement	100
Castner, H. Y. Alkali Metals	601	Cordner, Allen and Co. Purification of Water	239
Manufacture of Sodium	538	Cornelius, H., and Pechmann, H. von. Synthesis of Orcinol	181
Cattanaach, D. D. Distillation and Concentration of Liquids	40	Cortin, W. T. Stop Valves for Acids, etc.	139
Cnudz, F. Treatment of Sewage	615	Confinable. See Meisel	472
Cavazzi, A. Explosive	516	Cowles, A. H. Electrolytic Treatment of Ores	331
Caventou. Crotonylene Tetrabromide	371	Cowles, E. H. and A. H. Aluminium Furnace (illus.)	206
Cawley, J. Cement	327	Craig, G. Treatment of Slags	152
Cazeneuve, P. Detection of Coal-tar Colours in Wine	178	Crampton, C. A. See Richardson	385
Detection of Acid Magenta	518	Crawford, W. W. Maturing Spirits in Bottles	431
Detection of Magentas	334	Cresson, B. F. Aniline Black	663
Cazeneuve, P., and Lepine. Non-poisonous Colours	230	Cresswell, C. N. Discussion on Treatment of Sewage	318

INDEX OF SUBJECTS.

	PAGE		PAGE
Accumulators, Electrical.	105, 246, 217, 331, 455, 514, 615, 676	Aluminium Sulphate, Detection of Free Sulphuric Acid in	617
Acetamide, Beta-Picoline from	585	Alumino-ferric Cake	19
Acetanilide	580	Amido-alizarin, Derivatives of	596
Acetic Acid Manufacture (illus.)	31	Amido-azobenzene	596
Acid Test for Oils	69, 282	Amidohrucine	391
Acetone, Action on Aniline	238	Amidodiphenylsulphonic Acid	376
Acetone-dicarboxylic Ether, Orcinol from	481	Amide Powder (an Explosive)	678
Acetophenone as a Hypnotic	388	Ammonia Carbonate used with Alumina Mordants	165
Acetopropionic Acid from Sugars	673	In Coal Gas, Estimation of	253
Acid, Removal of Waste, in Purification of Mineral Oils	160	From Coke, or Shale Coke	257
Taps and Valves	368	Dissolved in Glycerine for Ice Machines, etc.	235
Acids, Congo Red as Indicator for Free	511	Distillation of	167, 487
Distributor for (illus.)	487	From Galvaniser's Dross	615
Indicators for	392	Loss of, from Manure prevented by Gypsum	611
Treatment of Waste, from Purification of Naphtha	160	Manufacture	235
Etc., Valves for	159	Nitrate Manufacture	325
Aconite, North American	218	Process of Gas Purification (illus.)	415
Aconitine	390	As Reagent for Double Ketones	180
Aconitum Napellus, Alkaloids of	171	Soda Process (illus.)	166, 128, 129, 210, 533, 668
Acridine	595	Soda Process, Development of	413
Address of President at Annual Meeting	401	Soda Process, Origin of	322
Adulteration of Organic Colouring Matters	250	Still (illus.)	667
Agriculture, Use of Ferrous Sulphate in	133	Vapour Tension of	131
Air-blast Pyrometer	91	Ammoniacal Liquor, Composition of	635
Air, Carburetted	651	Liquor, Distillation of (illus.)	379
Carburetter for	522	Ammoniated Soap	329
Distillation by Means of Heated	40	Ammonium Bichromate	487
Filtration of	368	Chloride Decomposed by Magnesia (illus.)	483, 187
Fluids forced by Compressed	368	Chloride Manufacture	32, 241
Freed from Dust	653	Iethyolsulphonate	332
Gas	21	Nitrate, Solubility of Silver Chromate in	286
Oxygen and Nitrogen obtained from	40	Sulphide, Sulphuretted Hydrogen from	33
Pump for Laboratory Use (illus.)	503	Thiosulphate formed in Gas-generators	470
Of Schools and Dwellings	513	Amyl Acetate	249
Scrubber or Cleanser for	317	Analysis by Means of Electrolysis	351
Separating Dust from	231	Anchietine	390
Separation of Dust from	594	Aniline, Action of Acetone on	238
Thermometer (illus.)	509	Action on Manganese Brown	482
Treatment of Liquids with	105	Black	237, 663
Albumen, Blood	378	Black on Woven Fabrics	666
Reaction for	393	Condensation of Butaldehyde with	161
Separated from Peptones	513	Condensation of Isovaleraldehyde with	162
Alcohol, Determination of Fusel Oil in	498, 496	Furfuroaphthionate	377
Still for	613	Isomer of Benzidine formed from	317
Utilisation of Carbonic Acid from Manufacture of	92	Method of Estimating Nitrous Acid	633
Alginic Acid	218	Oils, Analysis of	178
Alizarates of Iron and Chromium	522	On Orcinol, Action of	549
Alizarin, Phthalenylamido	595	And Perchloromethylmercaptan Compounds	320
Present Price of	351	Red Colouration of Cotton produced by	322
Valuation of	72	Titration of	679
Alkali, Export of	355	Animal Fibre, Distinguishing Vegetable from	508
Metals, Production of	601	Animalcule, Free Acid in	511
Process, Employment of Hydrocarbons in	379	Anisol, Mononitro-	160
Trade, State of	102	Anona, Drugs from	332
Waste, Treatment of	167	Anthracene, Oxidation Product of	95
Waste, Treatment of Vines with	169	Anthracenes, Synthesis	321
Alkaline Carbonates, Silicates decomposed by	41	Anthragallol, Methyl-	599
Leys, Purification	325	Anthrapinacone	95
Silicates, Manufacture	33	Anthraquinone, Anthrapinacone from	95
Sulphates, Treatment of	167	Antifebrin	580
Alkaloids, Colour Reactions of	437	Antifouling Composition	102, 510
Reagent for	510	Composition for Ships, etc.	329
Alkanet Dye, Detection of	30	Antimonial Ores, Treatment of	323
Allanton	385	Antimonious Chloride as Mordant for Coal-tar Colours	590
Alloy for Mercurial Gilding	35	Antimony Chloride, Treatment of Dye-baths when using	663
Metallic	431, 452, 494	Lactate as a Mordant	183
Alum Cake	428	Mordants used in Hosiery Dyeing	301
Cake, Valuation of	73	Oxalate	239
Clay, Analyses of	17	Oxalate, Potassium, as a Mordant	165
Alumina	428	Oxalate, Value as Mordant	71, 97
Commercial Sulphate of	16	Oxide, Solubility in Alkaline Solution of Glycerine	165
Determination	41, 550	Potassium Oxalate, Estimation	596
Determination of Iron in Presence of	507	Production in Banyas	671
Estimated in Phosphates	152	Production in Blast Furnaces	328
Estimated in Presence of Phosphoric Acid	176	Sulphide, Action of Hydrochloric Acid on	20
Mordants, Carbonate of Ammonia used with	165	Antipyretic (Salol)	578, 580
Mordants on Cotton	331	Antiseptic	451
Titration of Soda in Presence of	679	Compound	499
Aluminium	608, 616	Preparations, Granulated	241
Alizarates	525	Saccharine as an	616
Alloys	209	Soap	609
Bronze	608, 616	Antiseptics	388
Chloride, Timber Preserved with	670	Apomorphine Hydrochloride, Colouration of Solutions	173
Electric Furnace for (illus.)	206	Apple Chios containing Zinc	498
Estimation in Presence of Phosphoric Acid	249	Aqueous Vapour, Influence on Oxidation of Hydrogen	211
Fatty Compounds as Thickeners for Oils	539	Arabinose, Action of Dilute Acids on	36, 673
Iron Alloy	329	Arbutin	332
Iron Separated from	41	Archil Paste, Detection of Magenta in	286
Mordants	526	Argol, Examination of	497
And Sodium Chloride	608	Aromatic Bases, Action on Manganese Brown	482
Soldering	431, 491	Arsenic Acid Determination	391, 510
Stearate for Thickening Oils	608	Detection of	617

	PAGE		PAGE
Arsenic, Detection of Traces in Water	84	Bleaching Compound	666
Determined in Iron Ores	547	Cotton, etc.	533
Determination in Ores	510	Fats, etc.	509
Eliminated from Hydrochloric Acid	602	Influence on Turkey-red Dyeing	239
Method of Freeing Alum Cake from Iron	20	Machine	322
Removed from Hydrochloric Acid	534	Oil, etc.	35
In Spanish Pyrites	296	Powder, Export of	356
Sulphuretted Hydrogen Free from	40	Powder, Rate of Loss of Chlorine	587
Arsenical Ores, Calciner for	428	Powder, Statistics of	412
Ashes, Purification of Water by Vitriolised	199	Powder, Valuation of	73
Asparagin	385	Blood, Utilisation of	675
Asparagus, Coniferin and Vanillin in	243	Blue Colours, Discrimination of	252
<i>Aspergillus Oryza</i> , used in Brewing by Japanese	170	For Laundry Purposes	523
Asphalt Varnish for Leather	609	Bluish-Black Colour	523
Atmosphere, Purification of (illus.)	572	Boiler Incrustation Preventive	94
Atropa Belladonna, Constituents of	456	Boilers, Anti-incrustator for	454
Belladonna, New Constituent of	249	Electrical Safety Apparatus for (illus.)	445
Atropine, Action of, as a Poison	352	Fusible Plugs for	233
Aurantiamarin	390	Gas-firing for	159
Auriferous Ores, Treatment of	494	For Paper Pulp	135, 676
Pyrites, Treatment of	382	Purifying Feed Water for	233
Autoclaves, Apparatus for Emptying (illus.)	652	Water Feeder for	367
Azobenzene Derivative	523	Bones, Extraction of Fat from	672
Azo-bodies, Bromo- and Nitro-derivatives	598	Bordeaux Red	164
Preparation of	27, 28	Boric Acid as an Antiseptic	613
Azo-colours	525, 595, 597	Brandy, Composition of	542
From Diamines	181, 182	Estimation of Fuel Oil in	546
From Naphthylamine	127, 428	Brass, Action of Oils on	262
Produced on Cotton	600	Corrosion by Saline Waters and Acids	84
Produced on Fibre	96	Bread	171
Azo-compounds	596	Breeze, Arrangements for Burning	425
Mixed	26	Breweries, Fuel Consumed in	612
Azo-dyes	428	Brewers' Grains, Treatment of	542
Azo-naphthalene	258	Brewing	36, 104, 244
Azo-opiamic Acid	319	Hops Saved in	453
Azophenylene	661	Japanese	170
Azophosphines	523	Materials, Testing	542
Azotometer (illus.)	505	Potassium Isobisulphite Used in	170
		Utilisation of Spent Hops	244
Bacteriological Examination of Water	334	Bricks from Carbonaceous Clay	671
Bacteriology	261	Refractory	102
Baku Petroleum (illus.)	472, 480	Brimstone, Comparison of Pyrites with	98
Bakul	661	Bromine Absorptions of Oils	68, 282
Balance, Westphal's Hydrostatic (illus.)	65	In Sea Water, Amount of	40
Balances, Chemical	219	Bromazobenzene	598
Barium Binoxide	428	Bromopseudoecumenesulphonic Acids	375
Carbonate, Decarbonation of	165, 324	Bromosuccinic Acid, Inactive Malic Acid from	240
Chloride and Hydrate	430	Bronze	282
Hydrate	379	Brucine	390, 616
Oxide, Manufacture of Anhydrous	31	Burettes, Gas (illus.)	285
Barley, Germination of	104	Butaldehyde, Condensation with Aniline	161
Raffinose in	36	Butter, Detection of Artificial	618
Sugars in	36	In Milk, Determination of	198
Barometer, Influence on Blast Furnaces	168	Rancidity of	542
Basic Cinder, Manurial Value of	640	Treatment of Rancid	613
<i>Bassia</i> , Gutta-percha from	168	Butylaniline, Normal	161
<i>Bassia Parkii</i> , Gutta-percha from	329		
Batteries, Cement for Electrical	172	Cadmium, Separation from Copper	510
Elements for	615	Separation of Zinc from	41
Galvanic	247, 388, 455, 456, 511, 545, 675, 676	Calcination of Spanish Pyrites	296
Galvanic and Secondary	106, 331, 509	Calciner for Ores	167, 428
Insulating Material for	172	Calcium Acetate, Action on Ferric Alizarate	521
Regulating supply to Electric	616	Acetate, Valuation of	457
Secondary	246, 247, 454, 544	Alizarates	325
Thermo-electric	561	Bisulphite	31
Bauxite, Analyses of	17	Carbonate, Dissociation of	483
Beer, Apparatus for Raising	244	Carbonate, Solution in Carbonic Acid	324
Charged with Carbonic Acid	36	Chloride, Chlorine made from	32
Detection of Salicylic Acid in	618	Chloride, Utilisation of Liquors	35
Finings	613	Oxide, Solubility of	450
Finings for Beer	674	Phosphates from Slag	537
Glycerin Estimated in	457	Saccharate	453
Liquorice Detected in	508	Calico Printing on Both Sides	666
From Maize, etc.	453	Calorimeter (illus.)	159, 581
Non-intoxicating	404	Candles	608
Returns, Treatment of (illus.)	434	Hygienic	499
Worts, Acrating	674	Cane Sugar, Honey adulterated with	479
Beet, Extraction of Sugar from	243	Caoutchouc Manufacture	495
Juice, Influence of Alkalinity	612	Solubility of	168
Juice, Valuation of	612	<i>Carapa</i> , Drugs from	310
Melitose present in	169	Carbolic Acid, Discolouration of	160
Root Seeds, Germination of	212	Acid, Estimation of Phenol in	547
Sugar, Alcoholic Extraction of	169	Acid Manufacture	426
Bellit (an Explosive)	457	Acid, Valuation of	618
Benzene, Annual Consumption of	351	Carbon Alum for Treatment of Sewage	451
Containing Thiophen	480	Bisulphide Manufacture	167
Vapour Tension of	3	Determination by Chromic Acid	617
Benzenetrissulphonic Acid	377	Determination, Combustion Tube for (illus.)	333
Benzenoid Hydrocarbons	374	Dioxide, Behaviour with Hydrogen	139
Benidine Azo-colours	597	Dioxide used with Sulphur Dioxide in Ice Machines	431
Isomeric, formed from Aniline	317	Element of Batteries	531
Benzoic Acid, Reagent for	393	Filaments for Electric Lamps	615
Benzenophenone, Homologues of	321	In Iron, Colour Test for (illus.)	586
Trimethyldiamido	318	In Iron and Steel, State of	493
Benzoylsulphimide	75	Monochloride	232
Benzylhydroxanthranol	26	From Shale used with Sewage Sludge	675
Beverages, Lactic Acid used in	616	In Steel, Condition of	538
Bichromate of Soda Manufacture	33	Carbonates, Testing (illus.)	115
Bichromates, Valuation of	72	Carbonic Acid, Action on Slag	520, 667
Bilberries, Citric Acid from	240	Acid Apparatus (illus.)	36
Bituminous Products, Hardening	103	Acid, Beer charged with	36
Black Substance from Spent Lime of Sugar Works	674	Acid in Coal Gas, Estimation of	285
Blast Furnaces, Cyanogen Products from	334	Acid lost during Fermentation, Value of	92
Bleaching Apparatus (illus.)	661	Acid Manufacture	668

	PAGE		PAGE
Carbonic Acid, Measurer for Liquid (illus.)	326	Cocaine	174
Acid, Solution of Calcium Carbonate in	321	Artificial Formation of	10
Acid, Washing Precipitates in Air free from (illus.)	307	Reactions for	335
Oxide and Hydrogen, Combustion of	370	Coccerin from Living Cochineal	319
Oxide, Preparation of	391	Cocethyline	40
Oxide and Water, Reaction at High Temperatures	21	Cochineal, Coccerin from Living	319
Carbons for Batteries	515	Constitution of	29
For Electric Lamps, etc.	172, 451	Dyeing with	528
Carburetter for Coal Gas	522	Codeia, Production of	332
For Gas and Air	24, 373	Cerulein, Dyeing with	528
Carburetting Compound	651	Coke, Condition of Sulphur in	521
Gas	236	Determination of Nitrogen (illus.)	506
Carmine, Bromo	29	Estimation of Sulphur in	154
Castings, Malleable	607	As a Filtering Medium for Water	262
Cast-iron Pipes, Tarrad	37	Heating Value of	425
Cells, Absorption of Dyes by Living	600	Ovens	375
Cellulose extracted from Wood	106	Value in Blast Furnace	167
Cement	100, 101, 327, 328, 381, 536	Coke and Tar mixed as Fuel for Gas Generators	171
Damp-proof and Luminous	327	Coking, Coal Compressed for	317
From Debris of Roads	671	Colcothar, Composition of	30
Effect of Adulterations on	196	Collars, Cuffs, etc., made from Nitrocellulose	35
From Furnace Slags	241	Colonies of Microphytes in Water	114
The Hardening of	492	Colouring Matter from Cotton-seed Oil	205
Influence of Magnesia in	492	Matters	661, 662
Kiln	100, 605	Matters, Azo, from Paranitraniline	523
Manufacture	31, 151, 594	Matters, Detection of Organic	219
Mixed with Slag, Influence of Frost on	492	Colours, Influence of Steaming on Fastness of	532
Testing Portland (illus.)	188	Influence of Substitution on Shade of	597
Cements	602, 603, 604	Combustion	594
Centrifugal Machines	91	Determination of Heat of (illus.)	159
Machines, Use of	61	Compression, Heat produced by	516
Cereals, Sugars of	36	Concrete	100, 381
Cerite, Treatment of	522	Condenser for Gas	24
Cerium Salts, Purification of	522	Cocessine	501
Charcoal, Animal, Influence of Heat on Action of	167	Congo Red	419, 595
Value in Blast Furnace	351	As an Indicator	73, 511, 679
Chemical Industries, British	419	Coniferin in Asparagus	243
Chemicals, Comparative Values of	17	Copper, Actions of Oils on	363
China Clay, Composition of	76	Assay of Gold in	63
Grass	162	Corrosion by Saline Waters and Acids	81
Chinese Green	391	Detection of Traces in Water	84
Chlorides, Action on Antimonious Chloride as Mordant	480	Electrolytic Estimation of	54
Chlorine, Action on Benzene	451	Extraction from Pyrites	403
From By-product of Ammonia-soda Process	32	Ores, Valuation of	276, 277
From Chloride of Calcium	286	Oxide Asbestos used in Combustions (illus.)	333
Determination	587	Plates, Nickel-coated	331
Lost from Bleaching Powder	379, 402	Precipitate, Production from Spanish Pyrites	296
Manufacture	31	Precipitates, Purification of	242
Manufacture, Treatment of Liquors from	536	Production in Russia	683
Manufacture, Treatment of Residuals	457	Separation from Cadmium	510
Naphthol as a Test for Free	331	Valuation in Ores	48
Chloroform added during Fermentation	389	In Vines treated with Sulphate	169
Manufacture (illus.)	232	In Vines after Treatment	496
Products of Decomposition at Red Heat	578	Residuals, Utilisation of	325
Cholesterin	247	Wet Assay of	276, 277
Choline	167, 239, 241	Works, Treatment of Liquors from	31, 431
Chromates, Manufacture	605	Works, Treatment of Residuals	536
Chrome, Iron and Steel	617	Coprolite Deposits in Tunis	169
Chromic Acid, Carbon Determination by Means of	32, 523	Cord, Polishing Material for	672
Chromium Alizarates	586	Cordage, etc., rendered Waterproof	322
Chromometer (illus.)	532	Cork, Artificial	550
Chrysamin as a Mordant	456	Corundum, New Source of	210
Chrysotropic Acid	173	Cotton, Alumina Mordants on	531
Cinchona Bark, Africa (so-called)	248	Antimonious Chloride as Mordant on	590
Bark, Alkaloids of	210	Azo-Colours produced on	600
Citric Acid from Bilberries	215	Etc., Bleaching	533
Acid, Fermentation of	214	Fabrics Printed on Both Sides	666
Acid, Turmeric as Indicator for	456	Red Coloration produced by Aniline Vapour	322
Citrus Limetta, Oil of	519	Seed, Raffinose from	213, 386
Claret, Detection of Artificial Colour in	489	Seed Oil Refining	210
Clay, Analyses of	105	Silk of the Cameroons	612
Carbonaceous. Prepared for Filters	100	Waste, Extracting Grease from	608
Mill	671	Waste, Treatment of Dirty	671
Utilisation of Carbonaceous	165	Crank Pins, Pressure on	123
Cleansing and Washing, Fluid for	173	Creosol-carboxylic Acid	599
Clover, Nitrogenous Constituent of	558	Crotonylene	374
Coal, Annual Consumption for Gas	141	Crucibles	102, 382
Composition of South Staffordshire	317	Crystals extracted from Liquors during Evaporation	24
Compressed for Coke Ovens	521	"Cuirette" (Artificial Leather)	495, 496
Condition of Sulphur in	506	Cupels made of Magnesia	538
Determination of Nitrogen in (illus.)	167	Cupola with Steam Blast	451
Dust, Explosions caused by	236, 651	Customs Regulations	680
Dust, Utilisation of	154	Cyanogen Compounds, Manufacture	34
Estimation of Sulphur in	285	Products from Blast Furnaces	334
Coal-gas, Ammonia and Carbonic Acid in	655	Cymene in Rosin Spirit	595
Ammonia Purification of	522	Dehydrodivanillin	252
Carburetter for	373	Dehydromorphine	617
Enricher for	2, 424	Depilating Hides	609
Enrichment by Hydrocarbons	283	Desiccator, with Vacuum and Heater (illus.)	175
Estimation of Sulphur in (illus.)	13	Detergent	600
Explosion with Air	5	Dextrose, Action of Dilute Acids on	673
Extraction of Benzene from	653	Diabetes, Value of "Saccharine" in Cases of	76
Influence of Oxygen on Yield	522	Diamines, Azo-colours from	481, 482
Purification of Domestic Supply	95	Colours from Oxidation of Thio-bases of	164
Purifier	235, 246	Diazo-oxyacrylic Acid	381
Coal, Retort for	318	Dibromonaphthylamine	26
Coals, Carbonising with Recovery of By products	178	Dicthylaniline, Metamido- and Metanitro-	319
Coal-tar Colours in Wine	351	Digestion, Influence of Foods on	244
Derivatives, Prospects of	45	Digitalin	501
Durene in	160	Dihydroxydimethylanthraquinones, Isomeric	25
Thickening of	558	Diiodovinylamine	384
Utilisation of	172	Diethylallene	374
Cobalt, Manufacture	618	Dimethylaniline, Metamido- and Metanitro-	319
And Nickel, Separation			

	PAGE		PAGE
Dimethylaniline, Nitration of	376	Etching on Metals	102
Dinaphthylene	238	Ether, Vapour Tension of	134
Dinitrodurylic Acid	25	Viscosity of	149
Dinitronaphthol, Detection of	437	Ethylparaphenylenediamine	319
Dinitronaphthylamine	507	Ethylsulfaniline	319
Dinitropyromellitic Acid	25	<i>Eucalyptus Manna</i> , Raffinose from	213, 386
Dixytartaric Acid, Colours from	427	<i>Eucalyptus Staigeriana</i>	436
Diparaxylylcarbinol	320	<i>Eupatorium</i> , Drugs from	332
Diparaxylylketene	320	Eurhodines	320, 377
Diphenyl, Azo-dyes from	376	Eurhodol	320
Diphenylamine, Acridine from	395	Evaporating Apparatus (illus.)	316
Diphenylamine Reaction in Milk Analysis	618	Liquors	24
Reaction in Milk and Wine Analysis	516	Evaporation, Heat Abstracted by	133
Diphenyl-naphthaquinoxaline	26	Evaporator for Sea Water, etc.	521
Dipiperidyl formed from Nicotine	40	For Solutions, etc.	368
Dipendocumamol	27	Excitant, Solid Battery	676
Dise Stirrer in place of Glass Rod	80	Excreta, Treatment of	387, 675
Disinfectant	103, 499	Exhibition, Manchester Jubilee	577, 637
Composition	381	Explosion of Gases, Pressure caused by	12
Tablet	388	Temperature of	12
Disinfectants	434, 435	Explosions caused by Coal Dust	167
Disinfection of Sewage	614, 615	Explosive	546
Dissociation of Calcium Carbonate	483	Mixtures, Sprengel's	199
Distillation, Evils of Uninterrupted	330	Explosives	457, 502
Fractional (illus.)	333	Analysis (illus.)	677
By means of Heated Air	40	Manufacture and Treatment of	678, 679
Of Spirit under Diminished Pressure	331	Sprengel's	349
Distillers' Grains, Treatment of	512	Stability on Heating (illus.)	436
Distilling Apparatus (illus.)	234	Extraction Apparatus	175
Domestic Supply of Coal Gas, Purification of	522		
Donndake, Constituents of	435	Fabrics, Material for Dressing	672
Donndakine	173	Metallised Woven	388
Drinks, Non-Alcoholic	453	Treating and Washing	322
Drugs, New	332	Factories, Purification of Refuse Water from	543
Drums for Caustic Soda	666	Factory Drainage, Influence of, on Fish	214
For Soda, etc.	421	Fat extracted from Bones	672
Drying Apparatus for Laboratories	334	Fats, etc., Bleaching	609
Machine for Wool, etc.	322	The Drying of (illus.)	508
Oven for Laboratories	106	Examination of Oils containing Unsaponifiable	179
Durene, Action of Sulphuric Acid on	375	Mineral Oils estimated in	457
In Coal Tar	95	Saponification of	384
Derivatives	25	Specific Gravity of	67, 71
Durenequinone	25	Fatty Acids, Determination in Oils	311
Durenol	25	Feed Water for Boilers, Purifying	233
Dust, Air cleansed from	368	Felspar, Analysis of	489
Condensed by Electricity	172	Felting	378
Electrical Deposition of (illus.)	65, 572	Fennugreek Seeds, Alkaloids from	217
Separated from Air, etc.	231, 394, 653	Fermentation	331
Dwellings and Schools, Air of	543	Of Citric Acid	215
Dwellings, Water-closet System in	614	Influence of Thalline Salts on	434
Dye (Hematein)	600	In Pure Air	674
Dye-baths, Treatment for Antimony Chloride	603	Ferments, Preparation of	105
Dye-liquors, Ink from Waste	427	Ferriocyanides produced by Electrolysis	500
Dyeing	30	Ferro-Coke Filters for Water	264
With Alizarin	524, 528	Ferro-Phosphor	102
Apparatus (illus.)	661	Ferrocyanide Method of Freeing Alum Cake from Iron	20
Machine	97	Ferrous Oxide, Action on Vegetation	385
Machine for Woven Goods (illus.)	230	Fertilisers	433
Machine for Yarns, etc.	239	Fibre, Azo-colours produced on	96
Materials, Examination of	72	Distinguishing Animal from Vegetable	508
Silk, Wool, etc.	533	Etc., Gummy Matter removed from	428
Dyes, Absorption by Living Cells	600	Fibres, Treatment of Vegetable	161, 450
Export of German	353	Filaments for Electric Lamps	500
Fixation by Antimony Compounds	97	Filter (illus.)	423, 611, 621
Skin Irritation not caused by	301	Filters, (illus.) 368; 22, 23, 24, 105, 245, 246, 388, 441, 445, 468, 469	510
Dyestuffs	662	Filtering Apparatus	105
Adulterations in	286	Materials	262
Dynamic employed nt Hell Gate, New York	319	Filters, Efficacy of	391
		Filter for Laboratory Use	501
Egonine, Cocaine formed from	40	Self-regulating (illus.)	424
Education, Technical	565	Filters for Soda Liquor	671
Elaudin Reaction, The	339	Filter for Sugar Juice	350
Test for Oils	304	Filters for Sugar Liquor	101
Elastic Material	452	For Sugar Solution	233, 368, 441, 445, 469, 521
Electric Arc, Metals manipulated by	675	Filter Presses	416
Heat Indicator	316	Filtration of Large Quantities of Water (illus.)	171, 674, 675
Lamps, Carbons for	451	Filtration of Sewage, etc.	223, 644
Lamps, Filaments for	500	Of Water (illus.)	613
Lamps, Incandescent	511	Finings for Beer, etc.	674
Lamps, Material for Carbons	172	For Sour Beer	102
Electrical Deposition of Dust (illus.)	572	Fire Bricks	489
Deposition of Dust and Smoke	65	Fireclay, Analyses of	379
Deposition of Precipitates	388	Fire caused by Nitric Acid	96, 480
Purposes, Insulating Compound for	455	Fireproofing Composition	281
Safety Apparatus for Boilers (illus.)	445	Fire-resisting Cement	430
Treatment of Wines, etc.	453	Fisetin	430
Electricity, Smoke and Dust Condensed by	172	Fish, Influence of Drainage on	211
Electrodes from Carbonaceous Clay	671	Flashing Point of Petroleum	371
Electrolysis, Arrangement for Continuous	615	Flask, Fractionating (illus.)	631
Stand for (illus.)	499	For Gelatine Water Test (illus.)	114
Elbow Apparatus for (illus.)	500	Flour, Alkaloids in Old	171
Electrolytic Analysis	334	Paste, Determining Stiffness of	113
Formation of Ferriocyanides	500	Preservation of (illus.)	611
Reduction of Metals	331	Fluids Forced by Compressed Air	368
Separation of Metals	216, 675	Friction of	122
Separation of Zinc and Cadmium	41	Flux containing Chloride of Calcium	35
Treatment of Metals	451	Fodder from Waste Products of Paper-pulp	435
Treatment of Ores	431	Food, Edible Fungi valueless as	171
Treatment of Sulphides	99	Preservation of	37, 613, 671
Engine, Vapour and Hot Air Combined	316	Value of Inorganic Salts as	613
Eukines, Glycerine Solution of Ammonia used for	235	Foods, Influence on Digestion	214
Enrichment of Coal Gas	424	Inorganic	613
Esparto, Paper-pulp from	276	Formic Acid, Dibromhydroxycarboxybenzoyl	30
Esters or Ethers of Mineral Acids	523	Acid from Sugars	673

	PAGE		PAGE
Friction of Liquids and Solids	122	Globulin	387
Fruit, Preservation of	105	Glover Towers, Packing for	99
Fruit, etc., Preservation of	131	Glucose, Crystallised	453
Fuel, Artificial	317, 425, 427, 395	And Sucrose, Average Percentages in Sugar Cane	117
Blocks	236	Glycerin, Alkaline Solution of Antimony Oxide in	165
Comminuted	654	Ammonia Gas Dissolved in	255
Consumed in Breweries	612	Examination of Commercial	177
Determination of Calorific Value (illus.)	581	Manufacture	381, 431, 452
Patent	373	Still	329
Fuller's Earth employed to Bleach Fats	609	Valuation of	73
Fungi valueless as Food	171	Determination in Oils	282
Furfuralcohol	598	Determination in Oils and Fats	70
Furfuraldehyde, Colours from	377, 598	Estimated in Wine and Beer	157
Furfuronaphthylene	377	Determination	516
Furnace, Blast	607	Estimation in Wine	509
For Burning Tar	561	Glycerol. See Glycerin.	
Value of Charcoal and Coke in Blast	167	Gold Assay in Bar Copper	63
Furnaces fired with Tar	125	Employed in Colouring Glass	191
For Glass	100	Ores Treated by Galvanic Action	431
Heated by Hydrocarbons	236	Treatment of Ore containing	382
Hydrocarbon Feeder for (illus.)	471	(Chloride as Reagent for Albumen	393
Lining for	102, 608	Grain Gelatinised for Brewing	101
Lining for Metallurgical	491	Grass and other Fibres, Removal of Gum from	533
Regenerative	431, 591	Graduated Vessels with Strips of Opal Glass	652
For Smelting Pyrites	168	Grease extracted from Cotton Waste	608
Fusel Oil in Alcohol, Determination of	496, 498	Purification of	35
Estimation	393	Removed from Substances	102
Fuses for Explosive Shells and Torpedoes	679	From Wool, Composition of	539
Fusible Plugs for Boilers	253	Greasy Waste, Treatment of	383, 381
Fustic, Dyeing with	528	Green Colours, Discrimination of	252
Wood, Colouring Matter of	450	Schweinfurt	596
Fustin	450	Guaiaicum as Reagent for Turpentine Oil	393
		Guaiaum	385
		Gum removed from Chocolate Mordants	596
		Removed from Grass and other Fibres	523
Galactose, Action of Dilute Acids on	36, 673	Gummy Matter removed from Fibre by Pepsin	128
In Plants	386	Gunpowder Manufacture	157
Galvanised Iron, Treatment of Waste	151	Gut Prepared for Strings, etc.	384
Galvanisers' Dress, Utilisation of	615	Guttapercha from <i>Bassia</i>	168
Galvanising	101	From <i>Bassia Parkii</i>	329
Bath	172	Substitute for	221
Gamboge, Detection of	171	Gypsum preventing Loss of Ammonia from Manure	611
Gas Burner, Welsbach's	581	Sulphuric Acid made from	189
Burners, Atmospheric	535		
Burners, Incandescent	418, 522	Hamatein	600
Burettes (illus.)	285	Heat of Combustion, Determination of (illus.)	159
Carburetted	651	Electrical Battery actuated by	456
Carburetter	21	Produced by Compression of Air	316
Carburetting or Enriching	236	Regulator (illus.)	519
Condenser	21	Heating out of Contact with Products of Combustion	171
Engines, Phosphuretted Hydrogen as Igniter with	471	Oven for Laboratories	106
Fires for Boilers	159	Hercules Metal	209
Furnace for Iron Ore	608	Hesperidin	390
Furnaces	591	Hexachlorethane	232
Furnaces for Treatment of Ores, etc.	426	Hexachlorobenzene	232
Generator	95	Hexane, Action of Heat on	373
Generators, Ammonium Thiosulphate formed in	470	Hexylamylquinoline	161
Generators, Mixture of Coke and Tar as Fuel for	471	Hides, Removal of Hair from	495
Holder, Balanced (illus.)	472	Tanning	433, 510
Hydraulic Mains	317	Tawing	433
From Hydrocarbons	418	Treatment of	609
From Hydrocarbons and Oil	522	Honey, Adulterated	179
Lamps, Incandescent	421	Substitute for	153
Lamps, Regenerative	595	Hop Bitters	211
Liquor	655	Hopene	173, 171, 218
Made from Tar	5	Hops, Alkaloid of	173, 174
Making, Pitch employed in	522	Hops saved in Brewing	453
Manufacture	421	Treatment of	515
Manufacture from Oil	160	Hosiery Dyeing, Use of Antimony Mordants in	301
Producer	317, 522	Relation of Dyed, to Skin Irritation	226
Producers	421	Hydrastine	677
Purification, Ammonia Process (illus.)	415	Hydraulic Mains, Gas	317
Purification by Oxide of Iron	426	Hydrazinido-compounds	28
Regulator, Non-metallic (illus.)	175, 176	Hydrocarbons in Coal Gas	653
Residuals, Utilisation of	426	Combustion of, and Gas from	118
Retorts	235, 236	Employed in Alkali Process	379
Retorts for	318	Employed as Fuel	373
Statistics of Production	560	Enrichment of Coal Gas by	2
Water	471	Furnaces heated by	236
Gases, Ammonia from	235	Gas from	522
Apparatus for Absorption of	468	Purification of	419
Apparatus for Absorption by Liquids	423	Recovered from Aromatic Sulpho-Acids	317
Cooler for (illus.)	325	Hydrochloric Acid, Action on Nitrosodimethylaniline	597
In Hot Spring of Leuk	505	Acid detected in Vinegar	509
Regenerating Waste	160	Acid freed from Arsenic	602
Scrubber or Cleanser for	317	Acid from Chloride of Calcium	32
Specific Heats at High Temperatures	11	Acid, Purification of	531
Gaseous Fuel, Iron Manufacture with	212	Hydrocyanic Acid, Detection of	679
Gasoline, Vapour Tension of	3	Hydrofluoric Acid, Glass Etched by (illus.)	669
Gasometric Assaying (illus.)	115	Hydrogen Batteries	675
Gelatine Test for Water (illus.)	114	And Carbonic Oxide, Combustion of	370
Gelatins	381	Influence of Aqueous Vapour on Oxidation of	211
Germination of Peas and Wheat	385	Manufacture	160
Gilding, Alloy for Mercurial	35	Peroxide employed in Analysis	331
Glass	536	Peroxide, Estimation of	391
Glasgow Section, Chairman's Address to	390	Peroxide from Oxidation of Turpentine	9
Glass, Coloured or Opalescent	491	Peroxide used with Gas Referees' Sulphur Test	285
The Etching of (illus.)	669	Peroxide, Valuation of Chloride of Lime by	391
Gilding	536	Preparation of	391
Furnaces	100	Reaction with Carbonic Acid	24
Ornamental Designs on	99, 100	Hydroquinone. See Quinol	161
For Standard Thermometers	167	Hydroxyanthranol (Beta)	95
Transparent Paper as Substitute for	456	Hydroxystearic Acid	452
Vessels with Wire inserted	536	Hydroxythionaphthen	418, 119
Glazing Porcelain, etc.	491		

	PAGE		PAGE
Hypnone	388	Kaolin, Analyses of	189
Hyposulphates, Alkaline	324	Ultramarine from Japanese	166
Hypoxanthin	385	Kerosene, Examination of	176
		Ketones, Ammonia as Reagent for Double	180
Ice-making Machinery (illus.)	133, 158	Aromatic	321
Manufacture	22, 24, 124	Sulphonated Rosaniline a Test for	287
Incandescent Electric Lamps	514	Kiln for Cement	100
Gas Lamps	421	Cement	605
Gas Lamps, Material for	522		
Incrustation prevented in Boilers	454	Lactalbunin	387
Indiarubber	432	Lactate of Antimony as a Mordant	183
Commercial	211	Lactic Acid Manufacture	677
Dissolving Vulcanised	195	Acid used in Beverages	616
Plants, Fibre of German	182	Lactoglobulin	387
Soft Vulcanised	242	Lactucarius Plants, Utilisation of	195
Substitutes for	214	Lamp Oils, Comparison of	311
Tube	103	Lamps, Electric	615
Vulcanised	638	Mineral Oil	109
Indicator, Congo Red as an	73, 679	Lanolin	578, 671, 672
Indicators for Acids	392	Lanthanum Salts, Purification of	522
Alkalimetric	219, 437	Laundry Blue	523
Methyl-orange	287	Lead, Action of Oils on	363
For Sulphurous Acid	517	Autogenous Soldering of	431
Indigo, Substitutes for	661	Bin oxide used for Freeing Alum Cake from Iron	21
Indigo-blue, discharge on	182	Detection of Traces in Water	84
Indoanilines	28	Ores, Pigments from Waste	432
Indophenols	28	Sampling Zinc containing	537
Ink from Waste Dye-liquors	127	Steel Pots for	167
Inks, Marking	30	White	329, 539
Writing	30	White, Japanese Method of making	312
Insecticide	102	White, Manufacture	325
Institute at Zurich, Cost of	577	White, Substitute for	109
Insulating Compound	65	Leather, Artificial	133, 195, 496
Material	172, 609	Black Varnish for	609
Iodide Bath for Silvering	246	Dressing, Substitute for Urine in	496
Method of Copper Determination	51	Elastic	452
Iodine Absorptions of Oils	68, 282	Scrap prepared as Manure	104
Absorption Test for Oils	308	Treatment of	329
Colourless Solution of	332	Waste, Utilisation of	329
In Candles	199	Levulose, Action of Dilute Acids on	673
Solutions, Standardising	391	An Ether of	433
Test for Peppermint Oil	179	Oxidation of	170
Used with Gas Referees' Sulphur Test	281	Leys used in Fireless Steam Generators, Regeneration of	
Iodoform, Action of Light on	172	(illus.)	158
Aromatised	218	Lignite Clay as a Filtering Medium	105
Powder	501	Lime, Action on Metals	493
Iron, Action of Oils on	303	Chloride, See Bleaching Powder	73
Alizarates	523	Chloride, Ores acted on by	431
Aluminium Alloy of	329	Chloride, Valuation of	391
Cast, Strength of	289	Kilns	328
Chemistry of Foundry	289	Limit of Action on Sodium Carbonate	240
Chrome	605	Milk of	423
Coated with Tin, Lead or Zinc	452	Phosphate, Treatment of	696
Colour Test for Carbon in (illus.)	586	And Soda Method of Purifying Water (illus.)	267
Determination of Manganese in	508	Solubility of	450
Determination of Phosphorus in	176, 507, 569	From Sugar-works, Treatment of	671
Phosphide	104	Sulphate from Copper and Chlorine Residuals	536
Phosphide in Basic Slag	451	Treatment of Sewage with	451
Pigments from Copper Waste Liquor	536	Water	450
Puddled	382	Waters, Influence in Wool-dyeing	520
Removal of Metalloids from	605	Leaves, Oil of	436
Separated from Alum Cake	20	Liquids, Separation of Vapours from (illus.)	468
Separated from Aluminium	41	Liquorice in Beer detected	508
Silicon in	606	Lithographic Stones, Substitute for	49
And Steel direct from Ores	494	Liverpool Section, Chairman's Address to	565
And Steel, State of Carbon in	493	Lobelia Alkaloids	501
Sulphate used in Agriculture	433	Locomotives, Oil Burners for (illus.)	475
Tannate used in Filters	418	Logwood faced with Magenta	286
Toughened Cast	292	Lokain	162
Treatment of Spent Oxide	32	Lokanic Acid	162
Treatment of Waste Galvanised	451	Lokao	162
Wire Gauze, Waterproofed	671	Lokaonic Acid	162
Coke Filters for Water	265	Lubricant	102
Stone Carbonised for Filtering Purposes	675	Lubricating Compounds	609
Determination in presence of Alumina	507	Materials	329
Determination of Silicon in	502	Oils from Petroleum Residues (illus.)	382
Estimated in Phosphates	152	Value of Oils (illus.)	121
Estimation of Phosphorus in	106	Lupines, Treatment of	169
Estimated in presence of Phosphoric Acid	176, 219	Lupulin, Acids in Commercial	545
Extraction of Phosphorus from German	102		
Influence on Plants	610	Magdala Red	480
Malleable, direct from Ore	198	Magenta, Archil and Logwood adulterated with	286
Manufacture	101	Bases of	318
Manufacture with Gaseous Fuel	212	Manufacture (illus.)	163
"Mitis" Castings	209	Magentas, Detection of	334
Mixtures of Pig.	290	Reaction for Sulphonated	178
Ore, Gas Furnace for	608	Magnesia in Cement, Influence of	492
Ore, Pigments from	35	Crucibles, etc.	382
Ores, Arsenic determined in	547	Cupels made of	558
Ores, Treatment of	328	Used in Ammonia-soda Process, (illus.)	183, 487
Oxide, Manufacture	240	Waters, Influence in Wool-dyeing	530
Oxide, Purification of Gas by	426	Magnesium Chloride Manufacture	33
Isatin, Paramethyl, Derivatives of	237	Manufacture	31
Isinglass from Seaweed purified by Freezing	112	Sulphhydrate, Pure Sulphuretted Hydrogen from	240
Isoallylthylene	371	Maize, etc., Syrup and Beer from	153
Isobenzidine	347	Majolica Ware, Imitation	31
Isohesperidin	380	Maleic Acid, Inactive Maleic Acid from	240
Isohexane, Action of Heat on	373	Maleic Acid	240
Isovaleraldehyde, Condensation with Aniline	162	Malting	104
		Maltose	213
Japanese Kaolin, Ultramarine from	166	Manehoster Jubilee Exhibition	637
Jubilee Exhibition, Manchester	637	Section, Chairman's Address to	576
Kairin	581, 676	Yellow detected in Saffron	437

	PAGE		PAGE
Manganese Alloys	431	Mordant, Antimony Oxalate as a	239
Binoxide used for freeing Alum Cake from Iron	21	Chrysamin as a	532
Brown, Action of Aromatic Bases on	182	On Cotton, Antimonious Chloride as a	590
Determination	391	Potassium Antimony Oxalate as a	165
Determination in Iron	508	Mordanting Wool	526
Estimation	249, 365	Mordants	165, 183
Influence on Iron	291	Chocolate, Removal of Gum from	596
Voltaic Batteries	675	Morphine	391
Volumetric Test for	122, 167	Reactions for	509, 618
Manure, Basic Slag prepared as	433	Mortar Mill	100
Loss of Ammonia prevented by Gypsum	611	Mucilage from Cotton-seed Oil, Utilisation of	201
Phosphate Slag as a	161	Muffles	382
Phosphoric Acid used with	672	Mural Decoration, Composition for	603
Slag as a	330		
Stable	541	Naphthalene Colours	602
Value of Slag as a	101, 101, 212	Naphthalene-tetracarboxylic Acid	595
Manures, Estimation of Alumina and Iron in	152	Naphthas, Treatment of Spent Acids from Purification of	160
Testing Artificial	540	Naphthidine	238
Manurial Value of Basic Cinder	610	Naphthionic Acid	161, 376, 449
Manuring Experiments with Phosphates	100, 327	Naphthol as a test for Nitric Acid	157
Marble Imitation	511	Naphthols, Azo-dyes from	127, 428
Marsh-land, Experiments on	511	Naphthol-Alpha Sulphonic Acid (Beta)	29
Measure for Equal Quantities of (illus.)	235	Beta-Sulphonic Acid (Alpha)	28
Measurer for Liquid Carbonic Acid (illus.)	326	Naphtholcarbonates, Alkaline	482
Measures, Glass, with Strips of Opal Glass	652	Naphtholdisulphonic Acid	373
Meat Preparations, Analyses of	37	Acid, Colours from	164
Preservation of	57	Naphtholmonosulphonic Acid, Colours from	161
Medicines, Saccharine compounded with	677	Naphtholparadiazodiphenylsulphonic Acid	376
Medlar, Japanese	218	Naphtholtrisulphonic Acid	378
Meeting, Report of Fifth Annual	400	Naphthylamine, Action on Manganese Brown	482
Melittose from Cotton Seed, etc.	213	Beta, Azo-compounds of	28
From Molasses, etc.	386	Beta-, Action of Diazo-compounds on	26
Present in Beet	169	Dinitro-	597
In Sugar Products	101	Naphthylaminesulphonic Acid	449
Melting (of a Solid, Heat absorbed in the	111	Acids	376
Points, Determination (illus.)	617	Acids, Isomeric	161
Mentha Pip. and Vir., Comparison of Oils of	173	Beta-, Acid	481
Menthol Derivatives	156	Naphthylenediamine (Alpha-Beta-), Action of Diazo-compounds on	26
Menthylurethane	156	Naphthylenetoluquinoxaline	378
Menthylbenzoate	156	Naphthylhydrazines	374
Carbonate	156	Narcotics, Identification of	335
Phthalate	156	Newcastle Section, Chairman's Address to	584
Succinate	156	Nickel-coated Copper Plates	331
Mercurous Iodide, Solubility in Fats, etc.	218	Nickel and Cobalt Separation	618
Sulphate, Stability of	499	Distinguishing Coating of	619
Tannate	218	Manufacture	172
Mercury from Zinc-blende	534	On Plated Goods, Determination of	503
Biodide incorporated with Soap	600	Nicotine, Reduction	40
Electrodes, Cells with	500	Nitranilines, Diazoised	523
Mesitylene in Petroleum	25	From Nitrophenols	450
Metacresol	237	Nitrates, Nitrogen Determination in	510
Metal Plates, Pickling	191	Nitration of Dimethylaniline	376
Protecting Compound for	152	Nitrazobenzene	598
Metals, Action of Lime on	193	Nitric Acid Determination	617
Action of Oils on	362	Acid, Fire caused by	379
Action of Soda on	581	Acid, Naphthol as a Test for	457
Alloyed with Sulphides	34	Acid, Purification of	31
Detected in Drinking Water	81	Oxide, Degree of Solubility in Sulphuric Acid	82
Electrolytic Reduction of	331	Nitrification in Soil	510
Electrolytic Separation of	216	Nitrocellulose, Artificial Leather, etc., made from	35
Electrolytic Treatment of	151	Nitrometer, Alleged Error in Using	82
Galvanising or Coating	101	Application of (illus.)	505, 677
Manipulated by Electric Arc	675	Nitrogen in Coal, Determination (illus.)	506
Production of Alkali	601	Determination (illus.)	179, 180, 507, 510, 550, 510, 617
Separation by Electrolysis	675	Fixed by Soils	103
Separated from their Ores	101	Obtained from Air	40
Metallic Etching	102	Separated from Sulphuretted Hydrogen	33
Metallised Woven Fabrics	288	Nitrogenous (constituents of the Soil	169
Metalloids removed from Iron in Basic Furnace	605	Nitrophenols, Nitranilines from	450
Metaxylenol	257	Nitrosodimethylaniline, Action of Hydrochloric Acid on	597
Phenylazo-	318	Nitrothiokol	419
Methyl Alcohol in Plants	317	Nitrous Acid, Estimation	633
Methylanthragallol	399	Acid, Oxidation of	287
Methylene Blue	598	Njimo Wood	501
Methyl-orange not available as Indicator with Nitrites	287		
Methyl-violet, Bases of	318	Obituary, H. Sugden Evans	157
Formation with Perchloromethylmercaptan	320	James Muspratt	314
Methoxyl, Determination of	335	William Ripley Nichols	519
Mexican Customs Tariff	681	Oil, Adulterations in Olive	168
Micro-organisms in Drinking Water	511	Burners (illus.)	174
Microphytes in Potable Water	114	Examination of	494
Mildew on Vines, Copper Sulphate used to Destroy	169	Extraction of	102
Milk, Albumenoids of Cows	387	Gas	171
Analysis	546, 613, 618	Gas from	522
Determination of Butter in	198	Gas, Hydrocarbons from	374
Evaporated	613	Gas Manufacture	160
Pasteurised	198	Oxidised for Protecting Wire, etc.	432
Purifier	37	Oils, Action on Metals	362
Sugar, Decomposition by Hydrochloric Acid	672	For Batching Wool	383
Sugar Constituents in Plants	386	Containing Unsaponifiable Fats	179
Mineral Oil detected in Fat Oils	176	Detection of Mineral Oils in Fat	176
Oil Lamps	169	Examination of	503
Oil, Still for	376	Examination of Fixed (illus.)	65, 282
Oils estimated in Fats	157	Extracted from Waste	452
Oils, Removal of Waste Acid in Purification of	160	Fragrant Essential	436
Statistics, Prussian	682	Increasing Viscosity of	608
Mint, Detection of Turpentine in Oil of	171	Lubricating, Refining	494
Oil of	173	Lubricating, "Thickener" for	539
"Mitis" Iron Castings	209	Maumene's Test for	150, 361
Molasses, Raffinose from	386	Mineral, Gas Furnaces for Distilling	594
Raffinose in	104	Oxidation of	494
Separation of Sugar from	612	Refining	452
Treatment of	213		
Monomethylanilinefurfuraniline	377

Quinaldine, By-products of	258	Silicon in Foundry Iron	666
Synthesis of	161	Influence on Iron	291
Quinine Bark, Official	388	In Iron, Determination of	502
Hydrate	501	Silk Cocoons, Treatment of	322
Sulphate	501	Cotton	612
Quinol, Action of Paratoluidine on	161	Dressing, Treatment of Liquors from	378
Quinoline, Paraxylo-	239	Size for	432
A Phenyl-	161	Silver Chromate, Solubility in Ammonium Nitrate	286
Raffinose in Barley	36	Silver, Distinguishing Coating of	619
From Molasses, etc.	386	Estimated in Burnt Pyrites	548
Present in Beet	169	Silvering, Iodide Bath for	246
Present in Sugar Products	104	Size	672
Ragasin	661	For Raw Silk	432
Rags, Waste, etc., Treatment of	322	Skin Irritation not caused by Dyes	301
Rape Oil, Examination of	303	Irritation, Relation of Dyed Hosiery to	226
Red Colours, Discrimination of	250	Slag, Action of Carbonic Acid on the Thomas-	381
Red Liquor, Valuation of	73	Cement	603
Red, Magdala	480	Cement from	241
Refrigerators	22, 21	Composition of Basic	606
Refrigerators (illus.)	133, 158	Determination of Phosphoric Acid in	392, 502
Resin-acid Ethers for Varnishes	523	Influence of Frost on Cement mixed with	492
Resin Oil detected in Fat Oils	176	Iron Phosphide in Basic	451
Resinous Compounds, Hardening	103	As a Manure	101, 101, 330, 433
Resins, Action of Potash on	221	Phosphatic, as a Manure	161
Bleaching and Refining	539	Rich Phosphates from	537
Manufacture of Turpentine from	318	From the Thomas process	242
Reactions of	168	The Thomas	329
Resorcin Blue	662	Treatment of	452, 492
Resorcinol, Action of Paratoluidine on	161	Treatment of Sewage with Phosphoric	245
Reactions for	580	Utilisation of	387
Resorcinolparadiazodiphenylsulphonic Acid	376	Utilisation of the Thomas	385
Retort Furnaces Fired with Tar	125	Utilisation and Treatment of	672
Rhamnus, Colouring Matter from	162	Slags, Alkaline Phosphates from	379
Rhea Fibre	76	Slate Rubbish, Utilisation of	100
Rhea Fibres, Treatment of	450	Smoke Condensed by Electricity	172
Rivers, Pollution of	498	Electrical Deposition of (illus.)	572
Purification Bill, Rejection of	157	Soap, Ammoniated	329
Rosaniline, Chlorine Derivatives of	397	Antiseptic	609
Employed in Testing for Ketones	287	Disinfectant	102
Salts, Detection of	287	Liquid	452
Rosanilines, Reaction for Sulphonated	178	Manufacture	495, 671
Rosin determined in Soaps	392	Paste for Wool, etc.	329
Spirit	10	Solutions, Viscosity of	91
Spirit, Cymene in	595	Toilet	608
Treated with Oxide of Zinc	432	Soaps, Action of Chloride of Sodium on Solutions	90
Rubber, Vulcanised	35	Determination of Rosin	392
Vulcanising	101	Soap-suds, Utilisation of	102
Saccharate of Lime	453	Soda, Action on Metals	381
Saccharine	349, 350, 421	Ammonia Process (illus.)	533
Admixture with Medicines	677	Ammonia Process, Chlorine from By-products	451
As an Antiseptic	616	Bicarbonate, Manufacture	325
Detected in Sugar	546	Bichromate, Manufacture	33
Influence on Sugar Industry	612	Carbonate direct from Sulphate	613
A Sweetening Agent from Coal Tar	75	Carbonate, Manufacture (illus.)	166, 668
Saccharimeter, Portable (illus.)	8	Caustic, Manufacture	31
Saccharomyces Mycoderma, Action on Citric Acid	216	Crystals (Ammonia Process)	138
Safranin	398	Drums for Caustic	666
Magdala-red as a	480	History of Solid Caustic	283
Safranines	319	And Lime Method of Purifying Water (illus.)	267
Saffron, Detection of Manchester-yellow in	137	Liquor, Filters for	424
Sake (Japanese Beer)	170	Magnesia used in connection with Ammonia Process	183
Salicylic Acid, Detection	618	(illus.)	487
Acid, Manufacture	501	Manufacture, Improvements in	407
Acid, Paramethyl-	237	Metallic Drums for, etc.	424
Salicylphenylether (Salol)	577, 580	Nitrate, Extraction of	326
Salol	501, 677	Origin of Ammonia Process	322
Manufacture of	577	Titration in presence of Alumina	679
Salts, Specific Gravities of	601	Treatment of Bicarbonate	210
Value of Inorganic, as Food	613	White Caustic	351
Sampling Viscid Liquids (illus.)	211	Sodium Bicarbonate (illus.)	129
Sand, Influence on Cement	194	Carbonate, Limit of Action of Lime on	240
Sand-iron Ore, Paint made with	35	Chloride, Action on Soap Solutions	90
"Sanitas," Fluid and Oil	8	Chloride, Decomposition of Phosphate by	571
Santonin, Constitution and Derivatives of	40	Chloride Determined in presence of Potassium (chloride 10	239, 241
Saponaceous Material	284	Chromate	538
Saponification of Oils, etc.	131, 132	Manufacture	571
Test for Oils	309	Nitrate, Decomposition of Phosphate by	571
Schools and Dwellings, Air of	513	Sulphides, Hydrated	534
Schweinfurt-green	596	Thiosulphate for Clarifying Syrups	169
Scrubber or Washer for Gases	423	Soil, Nitrifying Organisms in	540
Sea-water, Amount of Bromine in	40	Nitrogen in the	169
Evaporator for	521	Soils, Fixation of Nitrogen by	103
Seaweed, Isinglass from, Purified by Freezing	142	Soldering	131
Selenides from the Andes, Analyses of	34	Solutions, Specific Gravities of	601
Selenium Cell applied to Photo-telegraphy	246	Sparteine	545
Separator for Substances of different sizes	94	Specific Gravities of Salts	601
Sesame Oil, Examination of	303	Gravity, Continuous Apparatus for	95
Settling Tank for Impure Water	368	Gravity of Fats, etc.	67, 71
Sewage, Cement made from	451	Spent Oxide Reoxidised without Removal	426
Chemical Treatment of	311	Oxide, Treatment of	32
Influence of, on Fish	214	Spindles, Pressure on	123
Purification of	38, 39, 611, 615	Spirit, Formation of Bad Crude	330
Treatment of	103, 171, 245, 246, 387, 451, 499, 671, 675	Spirits, Maturing	134
Shade Oil, Still for	376	Spreader for Liquids (illus.)	143
Sheep-wash	102	Standard Solution of Tartar Emetic, Preservation of	464
Shellac Algin	221	Starch, Examination of	72
Ship Sheathing	85	Manufacture	330
Ships' Bottoms, Anti-fouling Composition for	329	Paste, Determining Stiffness of	143
Composition for	35, 102, 195	Sugar, Honey Adulterated with	179
"Sig." Substitute for	496	In Tobacco Leaves	169
Silicates Decomposed by Alkaline Carbonates	117	Treatment of Waste Liquor	612

	PAGE		PAGE
Steam Blast, Cupola with	451	Sulphurous Acid from Zinc Blende	531
Boilers, Purification of Water for	158	Ores, Calciner for	428
Generators, Fireless (illus.)	158	Sylvic Acid	25
Spray, Apparatus for Tar, etc. (illus.)	471	Syphon (illus.)	141
Steaming, Influence on Fastness of Colours	532	Syringe for Sampling Viscid Liquids (illus.)	211
Steel, Bessemer	607	Syrup from Maize, etc.	453
Change of Texture on Heating and Cooling	538		
Chrome	605	Tank Liquors, Purification	325
Determination of Phosphorus in	176, 507, 509	Tannate of Mercury	218
Estimation of Phosphorus in	106	Tannin Determination	549
Direct from Ore	168	Estimation	179, 210
And Iron direct from Ores	494	Extracts, Examination of	495
Malleable Cast	607	Extracts, Treatment of	384
Manufacture	101, 328, 329, 382, 431	Tanning	423, 510, 609, 672
Progress of Basic Process	683	Tannins, Estimation of	79
Rails, Durability of	493	Tar and Coke mixed as Fuel for Gas Generators	471
Scrap added to Cast Iron	294	Composition and Value of	425
Still for Alcohol, etc.	613	Furnace for Burning	561
For Ammonia (illus.)	667	Gas made from	5
For Fragrant Essential Oils (illus.)	426	Products from	426
For Glycerine	329	Retort Furnaces fired with	425
For Shale Oil	376	Steam-spray, Apparatus for (illus.)	471
Stills for Petroleum (illus.)	473	Tariff Changes	681
Stirrer, Earthenware Disc used as	86	Tartaric Acid, Determination	497
Stone, Artificial	100, 327, 381, 451, 603	Acid with Tin Mordants	627
Glazed	381	Tartar Emetic, Preservation of Standard Solutions	464
Preserving	101	Emetic, Valuation of	71
Strainer for Tannin Determinations	82	Tartrazine (a Yellow Dye)	427
Straw, etc., Treatment for Paper	321	Tawing Hides	133
Strings, Gut	384	Tea, Theine determined in	178
Strontium Carbonate, Decarbonation of	163, 324	Technical Education	565, 585
Chloride and Hydrate	430	Temperature Regulator (illus.)	501
Hydrate	379	Terpene from Oil of Turpentine, Active	474
Hydrate, Manufacture	639	Tetrachloronaphthalene	378
Purification of Hydrate	33	Tetramethylbenzene	375
Saccharate Process	243	Tetrazo Colours	96

Society of Chemical Industry.

BYE-LAWS,

*AS AMENDED AT THE ANNUAL GENERAL MEETING AT LIVERPOOL,
JULY 14, 1886.*

1. The Association is to be known as "THE SOCIETY OF CHEMICAL INDUSTRY," and is established in accordance with the provisions of the Literary and Scientific Institutions Act, 1854.

OBJECTS.

2. The objects for which the Society is established are :—

A. To advance Applied Chemistry in all its branches.

B. To afford its Members opportunities for the interchange of ideas with respect to improvements in the various Chemical Industries ; and for the discussion of all matters bearing upon the practice of Applied Chemistry ; and to publish information thereupon.

C. To acquire and dispose of property for the purposes aforesaid.

D. To do all other things incidental or conducive to the attainment of the above-named objects, or any of them.

MANAGEMENT.

3. The whole of the affairs of the Society shall be managed by a Council, consisting of a President, twelve Vice-Presidents, twelve Ordinary Members of Council, a Treasurer, a Foreign Secretary, and the Chairmen and Honorary Secretaries of the various local Sections.

4. A General Secretary shall be appointed by the Council, which shall have power to pay him such salary as it may think fit. His duties shall be defined by the Council from time to time.

5. Two Auditors, at least one of whom shall be a Member of the Society, but not a Member of the Council, shall be elected at each Annual General Meeting, to examine the accounts and statements submitted by the Council : or a Professional Accountant may be appointed and paid out of the funds of the Society.

6. The Council for the time being shall be the custodian of the funds and property of the Society, and may invest or use the same in such a manner as the Council may think fit for the purposes of the Society as defined by its Bye-laws.

ELECTION OF OFFICE-BEARERS.

7. Except as otherwise provided by Bye-laws 4, 23, and 24, all office-bearers shall be elected at Annual General Meetings of the Society, and by ballot.

8. The persons to be submitted for election at Annual General Meetings to the offices of President, Vice-President, Honorary Treasurer, and Honorary Foreign Secretary, shall be nominated by the Council. Those to be submitted for election to the office of Ordinary Member of Council, shall be nominated as provided by Bye-laws 17, 18, and 19.

9. The Honorary Treasurer and the Honorary Foreign Secretary shall retire annually, but shall be eligible for re-election.

10. The President shall hold office for one year, retiring at the close of the Annual General Meeting next following that at which he was elected, but shall be eligible for re-election.

11. When the President who is about to retire is not nominated for re-election to the office of President, he shall always be one of the persons nominated by the Council for election to the office of Vice-President.

12. Four Vice-Presidents shall retire each year, and those who thus retire shall not be eligible for re-election to the Council, except under Bye-laws 23 and 24, until the Annual General Meeting next following that at which they retire. When a Vice-President is nominated by the Council for election to the office of President, the Vice-President thus nominated shall not be counted among the four Vice-Presidents who are to retire,

13. Except that any Vice-President may be nominated by the Council for election to the office of President, and that such Vice-President, if any, shall not be included in the operation of the present Bye-law, the Vice-Presidents shall retire as far as may be possible in the order in which they were elected. When the four who must retire cannot all be Vice-Presidents who have been in office for the longest period, such number of them as may be necessary shall be selected by the Council, by ballot, from among those of the Vice-Presidents who have been in office for the next longest period.

14. Any Member of the Society who is not in arrear with his subscriptions, except as otherwise provided by Bye-law 12, may be nominated and elected to the office of Vice-President.

15. Four Ordinary Members of Council shall retire each year, and those who thus retire shall not be eligible for re-election to the Council, except under Bye-laws 23 and 24, until the Annual General Meeting next following that at which they retire. When an Ordinary Member of Council is nominated for election to the office of President, and when an Ordinary Member or two or more Ordinary Members of Council may have been nominated for election to the office of Vice-President, the Member or Members so nominated shall not be counted among those who are to retire.

16. Except that any Ordinary Member of Council may be nominated for election to the office of President, or to that of Vice-President, and that the Members, if any, who have been so nominated, shall not be included in the operation of the present Bye-law, the Ordinary Members of Council shall retire as far as may be possible in the order in which they were elected. When the four who must retire cannot all be members who have been in office for the longest period, such number of them as may be necessary shall be selected by the Council, by ballot, from among those of the Ordinary Members of Council who have been in office for the next longest period.

17. If, by reason of any Ordinary Member of Council, or any two or more Ordinary Members of Council, having been nominated for election to the office of President, or to that of Vice-President, the number of Ordinary Members of Council to be elected at the ensuing Annual General Meeting shall be greater than four: the Council shall nominate the number in excess of four of the persons to be submitted to that Annual General Meeting for election as Ordinary Members of Council, and four shall be nominated as provided by Bye-laws 18 and 19.

18. At least two months before the date of each Annual General Meeting, the Council shall issue to each Member of the Society a list of the Council, showing which of its Members are to retire at the date of that meeting, and giving the names of the persons who have been nominated by the Council for election at that meeting to the office of Vice-President, and also the names of the persons, if any, who have been nominated by the Council under Bye-law 17 for election to the office of Ordinary Member of Council, and inviting nominations to the four of the vacancies about to occur, persons to fill which have not been nominated by the Council. Such nominations must be made upon a printed form, which will be supplied to any Member of the Society at his request, addressed to the General Secretary, and which form shall be as follows:—

SOCIETY OF CHEMICAL INDUSTRY.

*We, the undersigned Members of this Society, do hereby propose
..... of
in the County of as a candidate for elect on as a
Member of Council of the Society, and I, the said
am willing to stand for election, and if elected will endeavour to attend the
Council Meetings, and do all in my power to promote the welfare of the Society.*

(SIGNED)

15.....	30.....

No such nomination shall be valid unless it be signed by at least ten Members of the Society, who are not in arrear with their subscriptions, nor unless it be received by the General Secretary, at the Society's Office, at least one month before the date of the commencement of the Annual General Meeting, to the election to take place at which it refers. Nor shall any such nomination be valid if the person nominated be ineligible for election under Bye-law 12 or Bye-law 15. No Member shall sign more than one Nomination Form.

19. If the number of persons nominated, as provided by Bye-law 18, be fewer than four, the further number necessary shall be nominated by the Council.

20. A complete List of the Council, showing which of its Members will retire at the forthcoming Annual General Meeting, and the names of all persons who have been nominated for election at that meeting, shall be printed as a Ballot List, and this Ballot List shall be sent to each Member of the Society at least five days before the commencement of the said Meeting.

21. On the first day of the said Meeting, at such stage of its proceedings as shall be most convenient, the Members present shall hand their Ballot Lists to the General Secretary, or, in his absence, to such other person as the President may appoint. Members unable to attend the Meeting may send their Ballot Lists before the Meeting to the General Secretary in sealed envelopes. Each such sealed envelope must be marked **BALLOT LIST**, and must, moreover, have written upon it the name of the Member sending it. The names written upon such sealed envelope having been compared with the Society's Register by the General Secretary, such sealed envelopes shall be opened at the Meeting by Scrutators appointed by the Meeting. The Scrutators shall see that the conditions of the ballot are strictly fulfilled.

22. Any Member shall be at liberty to strike out any name or names of ordinary Members of Council printed on his voting paper, provided that the names so struck out are those in excess of the number of vacancies to be filled up.

23. If the office of President should become vacant by death or resignation during the period intervening between two Annual General Meetings, a new President shall be elected by the Council.

24. If any other vacancy shall occur in the Council during the period intervening between two Annual General Meetings, the Council shall elect a person to fill it until the next Annual General Meeting, when the Member who has been so elected by the Council shall retire, in addition to those who retire under Bye-laws 12 and 15. Such Member, however, shall be eligible for re-election, and shall be nominated for re-election at the Annual General Meeting next following his election by the Council.

MEMBERS AND THEIR CONTRIBUTIONS.

25. Every Candidate for admission as a Member of the Society must be proposed according to the form set out in Rule 26. He must be proposed by one or more Members to whom he is known personally. The proposal form must be sent duly signed to the General Secretary, who shall lay the same before the Council at its next Meeting. If the majority of the Members of Council present are in favour of his election, the candidate shall be declared duly elected, and his name shall be entered in the Register of the Society. At whatever period of the year a new Member may be elected, he shall be required (unless the Council shall determine otherwise) to pay his subscription for that year; having done which he shall be entitled to receive all the numbers of the Society's Journal for that year.

26. The Nomination Paper must take the following form, and may be obtained from the General Secretary, or from any of the Secretaries of Local Sections:—

THE SOCIETY OF CHEMICAL INDUSTRY.

(Candidate's Name in full)
is hereby proposed as a fit and proper person to become a Member of the
Society of Chemical Industry.

For Names only of
Members recommend-
ing the Candidate. }

Signature of Candidate

Address to which the
Candidate wishes the
Society's publications
to be sent, and which
is to be entered in the
Society's Register. }

Profession or Business
Occupation. }

Date

27. Each Member shall pay an annual subscription of Twenty-five Shillings, due on the First of January in each year; but any Member may pay a life composition fee of Fifteen Pounds in lieu of an annual subscription.

28. A List of the Members of the Society, with their addresses, shall be printed and distributed to each Member of the Society in the month of January in each year.

29. No person shall be entitled to the privileges of Membership who is in arrear with his subscription. No Member, whose subscription has not been paid, shall be entitled to attend Meetings or to vote, or to receive gratuitously any of the publications of the Society; and if the subscription be not paid within four months after further application from the Secretary, due notice shall be given to the Member, whereupon his name shall be struck off the register: he shall cease to have any right, privilege, or interest in the Society, and the arrears of subscription shall be recovered at law.

30. Any Member may withdraw from the Society at the end of any year, after giving notice to the General Secretary of his desire to withdraw, such notice to be accompanied by the payment of all arrears, if any, which may be due from him to the Society up to that date, and by such notice and payment he shall be released from all further liability as a Member.

MEETINGS.

31. The Council shall meet periodically, to examine accounts, to authorise payments, to act as a Committee of Finance, and to transact such business as may be necessary. Its meetings shall be convened by circular posted to all its Members, either by the order of the Council itself, given at a previous meeting, or by instruction from the President; and at any Meeting of the Council thus duly convened five Members shall constitute a quorum. The circular convening each Meeting shall be accompanied by an agenda paper, stating the nature of the business to transact which the meeting is called, and also by a list of candidates for membership, if any, who are to be proposed for election at such meeting, with the address and occupation of each such candidate.

32. For the furtherance of the objects of the Society, for advice, examination of and reports upon novelties, improvements, inventions, processes, or other matters of interest in connection with the chemical industries, the Council may appoint Special Committees, which may consist in part or entirely of persons other than Members of the Council. Such persons must be Members of the Society, and all Special Committees shall be under the control of the Council. The President for the year shall be the Chairman of all Special Committees, and the General Secretary of the Society shall be the Secretary of them, unless otherwise arranged by the Council.

33. No Special Committee, nor any Committee of Local Section, shall have any control over the funds of the Society, except to the extent to which funds for its use may be voted by the Council. An account of the manner in which any funds so voted for the use of any Committee have been expended shall be furnished to the Council on or before the 31st of December in each year.

34. An Annual General Meeting of the Members of the Society shall be held at such time and place as shall have been decided at the previous Annual General Meeting, to receive a Report from the Council, to elect office-bearers, to hear an address by the President, and to transact such other business as may be necessary or desirable, including, if the Council think fit, the reading and discussion of papers.

35. Notice of each Annual General Meeting shall be given in the Journal of the Society at least fourteen days before the day on which such Meeting is to commence.

36. The order of the business to be transacted at the Annual General Meetings shall be decided by the Council from time to time.

37. A Member may introduce one visitor at any General or Local Meeting of the Society. Such visitor may, by leave of the Chairman, take part in any discussion, but he shall not vote.

38. The Council may accept communications from gentlemen not Members of the Society, and allow them to be read before the Members.

MISCELLANEOUS.

39. If any person proposed to the Council for election as a Member of the Society be rejected, no record of his rejection shall be placed upon the minutes.

40. All papers proposed to be read before a General Meeting of the Society must be sent to the General Secretary fourteen days at least before the date of that Meeting. The Council shall allow them to be read or ask that they be amended, or reject them, as it thinks fit.

41. The Society shall have the right of priority of publication for three months of all communications made to the Society.

42. A Journal of the Society shall be published at least once a month, and shall be distributed gratuitously to the Members of the Society, except that no member of the Society shall be entitled to receive it who has not paid his subscription.

43. The author of any communication which has been read before the Society or before any of its Local Sections, and the publication of which in the Society's Journal has been authorised by the Council, may receive not more than fifty copies of such communication, together with the discussion thereon, if the author desires it, printed separately, provided that he gives notice of his desire to receive such copies upon the manuscript of his communication forwarded by him to the Editor of the Journal.

44. The Journal of the Society shall be edited and managed as the Council shall prescribe from time to time. Nothing shall appear in it, the publication of which has not been authorised by the Council, or by a Publication Committee appointed by the Council. It shall contain, in full or in abstract, as the Council may in each case decide, such of the communications read before the Society or any of its Local Sections as the Council may consider it desirable to publish, together with such other matter, relating to applied chemistry and the practice thereof, as the Council may from time to time direct.

LOCAL SECTIONS.

45. Upon receiving a requisition signed by at least thirty Members of the Society from any particular district, the Council shall consider the advisability of allowing a Local Section for that district to be formed.

46. Each Local Section may make rules for its own government, but no such rules shall be valid unless and until they have been sanctioned by the Council of the Society, and such rules must in each case include the following provisions :—

(a) That the affairs of the Section shall be conducted by a Committee, which shall be elected by the Members of the Section, in such manner as the rules of the Section shall provide.

(b) That, except elections to fill up unforeseen vacancies, all elections to the Committee of a Local Section, and all election of Officers of the Section, whether such Officers be appointed by the Committee or otherwise, shall take place in the month of April, and that the names of the persons elected shall in each case be reported to the Council on or before the 20th of that month; but that the members of Committee and the officers thus elected or appointed in April shall not take office, and those whom they are to succeed shall not retire from office, in each case until the close of the session then current.

(c) That no modification of or addition to the rules of the Section shall be made without the consent of the Council of the Society.

47. When the Council has consented to the formation of a Local Section of the Society, and has approved the rules by which it is proposed that that Section shall be governed, the Chairman and Honorary Secretary of that Section shall be *ex-officio* Members of the Council of the Society.

48. Each Local Section shall be bound to defray its own expenses for printing, stationery, advertising, postage, reporting, and hire of rooms; but the Council shall make a grant in aid thereof out of the General Funds of the Society, or may, if it think fit, defray the whole thereof.

49. An account of the expenditure of each Local Section during the preceding twelve months shall be furnished to the Council on or before the 15th of June in each year.

50. Except for printing, stationery, advertising, reporting, postage, and hire of rooms, no Local Section shall incur any expense without having previously obtained the sanction of the Council thereto.

51. For the purpose of meeting its expenses, each Local Section may require its Members to pay a Sectional subscription, which, however, shall not exceed Five Shillings per annum.

52. Every Member of the Society shall be entitled to attend, and to take part in the proceedings of the meetings of all Local Sections, except meetings concerning the business management of any Section of which he is not a Member.

53. The Committees of Local Sections shall have power to accept or reject communications proposed to be read before such Sections.

ALTERATION OF THE BYE-LAWS.

54. Any Member of the Council may submit to the Council in writing any proposal to alter or add to the present Bye-laws, and the Council may submit such proposal to the ensuing Annual General Meeting, if it think fit; but the Council shall submit such proposal to such Annual General Meeting, on a requisition to that effect, signed by at least Twenty Members of the Society, who are not in arrear with their subscriptions, provided that no proposed alterations of, or additions to the Bye-laws shall be considered at any Annual General Meeting, unless at least one month's notice thereof has been posted to every Member of the Society.

EXTRAORDINARY MEETINGS.

55. Extraordinary General Meetings of the Society may be convened at any time by the President and Council, or on receipt of a written requisition, signed by at least Thirty Members of the Society. The circular calling the Meeting must state the objects thereof, and must be delivered or sent by post to each Member of the Society at least fourteen days before the proposed Meeting is to take place.

LIST OF MEMBERS.

A

Abbott, John, Braemar House, Lancaster Gate, Hyde Park, W.
 Abel, Sir F. A., Royal Arsenal, Woolwich, London, S.E.
 Abney, W. de W., Willeslie House, Wetherby Road, South Kensington, S.W.
 Abraham, A. C., 87, Bold Street, Liverpool
 Acland, Sir H. W., Radcliffe Library, Oxford
 Adam, A. Learmonth, 18, Robertson St., Greenock, N.B.
 Adam, J. B., 172, Leith Walk, Edinburgh
 Adams, M. A., Ashford Road, Maidstone, Kent
 Adams, J. W., 74, Oxford Street, Regent Road, Salford, Manchester
 Addenbrooke, Edwin, 18, Cawley Rd., South Hackney, E.
 Addie, J., Langloan Ironworks, Coatbridge, N.B.
 Addyman, F. T., 17, Tenmyson Street, Nottingham
 Adkins, H., Chemical Works, Smethwick
 Adleck, J. Mill House, Woolton, near Liverpool
 Aikman, Charles M., Middlefield House, Partick Hill, Glasgow
 Aitken, A. P., S. Clyde Street, Edinburgh
 Akitt, Thomas, 3, Victoria Road, Leuzie, N.B.
 Albright, G. S., The Elms, Park Road, Edgbaston
 Albright, W. A., Mariemout, Birmingham
 Alexander, J. O., Pln. Taschen de Vrienden, West Coast, Demerara
 Alexander, W. T., 20, Booth St., Mosley St., Manchester, and Crummock Bank, Victoria Crescent, Eccles
 Allan, Jno., 2, Blythwood Villas, Crouch Hill, London, N.
 Alldred, C. H., 35, Crisp Terrace, Upper Park Road, Plumstead Common, Kent
 Allen, A. H., 6, Ash Mount, Broom Hill, Sheffield
 Allen, J., 164, Upper North Street, Poplar, London, E.
 Allen, J. Fenwick, Newham, Whalley Range, Manchester
 Allen, Walter S., 13, Beacon St., Boston, Mass., U.S.A.
 Allen, Wm., Edenholme, Bournemouth, Hants
 Allen, W. H., c/o F. Stearns & Co., Detroit, Mich., U.S.A.
 Allender, G. M., Stammerham, Horsham, Sussex
 Allhusen, A., Gateshead-on-Tyne
 Allhusen, Wilton, 102, Quay Side, Newcastle-on-Tyne
 Allison, G. H., Seaview, Litherland Park, nr. Liverpool
 Alsberg, M. (Sondheim, Alsberg & Co.), P.O. Box 2437, New York, U.S.A.
 Anderson, C. Torre, Messrs. Bass & Co., Burton-on-Trent
 Anderson, Geo. B., Victoria Square, Felling-on-Tyne
 Anderson, John, Cambroie Ironworks, Coatbridge, N.B.
 Anderton, G. H., Howendyke, Howden, Yorks.
 Angell, J., The Grammar School, Manchester
 Angus, James, Lugar, Ayrshire, N.B.
 Angus, John, 47, Lime Street, E.C.
 Angus, W. Mathwin, St. John's Leather Works, Newcastle-on-Tyne
 Annandale, J. H., Polton, Midlothian, N.B.
 Ansdell, G., 45, Courtfield Rd., South Kensington, S.W.
 Ansdell, T. C., Kearsley Cottage, Farnworth, Bolton
 Anthony, J. M., c/o E. G. Marks, St. Augustine's Chambers, Unity Street, Bristol

Archbold, George, Chemical and Optical Laboratories, Oswego City, New York, U.S.A.
 Archbutt, L., Argyle Terrace, Rose Hill, Derby
 Arcimis, Aug., 43, Paseo de las Acacias, Madrid
 Armstrong, H. E., Central Institution, Exhibition Road, London, S.W.
 Armstrong, Sir William G., Newcastle-upon-Tyne
 Arnott, G. W., Messrs. Arnott & Button, Rainham, Essex
 Arthur, W. (present address unknown).
 Ash, T. E., 8, Deanery Road, Brompton Road, London, E.
 Ashwell, H., Woodthorpe Grange, Sherwood, Nottingham
 Ashwell, J. H., Woodthorpe Grange, Sherwood, Nottingham
 Ashwell, J. R., Midanbury Lodge, Bentinck Road, The Forest, Nottingham
 Ashworth, L., The Barlows, Radcliffe, near Manchester
 Aston, Theo., 11, New Square, Lincoln's Inn, London, W.C.
 Atcherley, R. J., 37, Ashchurch Grove, Starch Green, W.
 Atkins, S. R., Market Place, Salisbury
 Atkinson, A. J., 44, Londonn Square, Cardiff
 Atkinson, Geo., Aldersgate Chemical Works, Southall, Middlesex; and 66 Aldersgate Street, London, E.C.
 Atkinson, R. W., 44, Londonn Square, Cardiff
 Attfield, J., Ashlands, Watford, Hertfordshire
 Aubrey, W. H., Caledonia Estate, Province Wellesley, Penang
 Auerbach, C. G., Farbenfabriken vorm. F. Bayer & Co., Elberfeld, Germany
 Austin, E., 126, Bermondsey Street, London, S.E.
 Aykroyd, W. H., Oakwood Villas, Toller Lane, Marningham, Bradford, Yorks.

B

Bailey, Edwin M., Royal Bank of Scotland, Ardrossan, Ayrshire, and 38, Berkeley Street, Glasgow
 Bailey, Wm., The Terrace, Oaken, near Wolverhampton
 Bailey, G. H., Owens College, Manchester

Society of Chemical Industry.

BYE-LAWS,

*AS AMENDED AT THE ANNUAL GENERAL MEETING AT LIVERPOOL,
JULY 14, 1886.*

1. The Association is to be known as "THE SOCIETY OF CHEMICAL INDUSTRY," and is established in accordance with the provisions of the Literary and Scientific Institutions Act, 1854.

OBJECTS.

2. The objects for which the Society is established are :—

- A. To advance Applied Chemistry in all its branches.
- B. To afford its Members opportunities for the interchange of ideas with respect to improvements in the various Chemical Industries ; and for the discussion of all matters bearing upon the practice of Applied Chemistry ; and to publish information thereupon.
- C. To acquire and dispose of property for the purposes aforesaid.
- D. To do all other things incidental or conducive to the attainment of the above-named objects, or any of them.

MANAGEMENT.

3. The whole of the affairs of the Society shall be managed by a Council, consisting of a President, twelve Vice-Presidents, twelve Ordinary Members of Council, a Treasurer, a Foreign Secretary, and the Chairmen and Honorary Secretaries of the various Local Sections.

4. A General Secretary shall be appointed by the Council, which shall have power to pay him such salary as it may think fit. His duties shall be defined by the Council from time to time.

5. Two Auditors, at least one of whom shall be a Member of the Society, but not a Member of the Council, shall be elected at each Annual General Meeting, to examine the accounts and statements submitted by the Council: or a Professional Accountant may be appointed and paid out of the funds of the Society.

6. The Council for the time being shall be the custodian of the funds and property of the Society, and may invest or use the same in such a manner as the Council may think fit for the purposes of the Society as defined by its Bye-laws.

ELECTION OF OFFICE-BEARERS.

7. Except as otherwise provided by Bye-laws 4, 23, and 24, all office-bearers shall be elected at Annual General Meetings of the Society, and by ballot.

8. The persons to be submitted for election at Annual General Meetings to the offices of President, Vice-President, Honorary Treasurer, and Honorary Foreign Secretary, shall be nominated by the Council. Those to be submitted for election to the office of Ordinary Member of Council, shall be nominated as provided by Bye-laws 17, 18, and 19.

9. The Honorary Treasurer and the Honorary Foreign Secretary shall retire annually, but shall be eligible for re-election.

10. The President shall hold office for one year, retiring at the close of the Annual General Meeting next following that at which he was elected, but shall be eligible for re-election.

11. When the President who is about to retire is not nominated for re-election to the office of President, he shall always be one of the persons nominated by the Council for election to the office of Vice-President.

12. Four Vice-Presidents shall retire each year, and those who thus retire shall not be eligible for re-election to the Council, except under Bye-laws 23 and 24, until the Annual General Meeting next following that at which they retire. When a Vice-President is nominated by the Council for election to the office of President, the Vice-President thus nominated shall not be counted among the four Vice-Presidents who are to retire.

13. Except that any Vice-President may be nominated by the Council for election to the office of President, and that such Vice-President, if any, shall not be included in the operation of the present Bye-law, the Vice-Presidents shall retire as far as may be possible in the order in which they were elected. When the four who must retire cannot all be Vice-Presidents who have been in office for the longest period, such number of them as may be necessary shall be selected by the Council, by ballot, from among those of the Vice-Presidents who have been in office for the next longest period.

14. Any Member of the Society who is not in arrear with his subscriptions, except as otherwise provided by Bye-law 12, may be nominated and elected to the office of Vice-President.

15. Four Ordinary Members of Council shall retire each year, and those who thus retire shall not be eligible for re-election to the Council, except under Bye-laws 23 and 24, until the Annual General Meeting next following that at which they retire. When an Ordinary Member of Council is nominated for election to the office of President, and when an Ordinary Member or two or more Ordinary Members of Council may have been nominated for election to the office of Vice-President, the Member or Members so nominated shall not be counted among those who are to retire.

16. Except that any Ordinary Member of Council may be nominated for election to the office of President, or to that of Vice-President, and that the Members, if any, who have been so nominated shall not be included in the operation of the present Bye-law, the Ordinary Members of Council shall retire as far as may be possible in the order in which they were elected. When the four who must retire cannot all be Members who have been in office for the longest period, such number of them as may be necessary shall be selected by the Council, by ballot, from among those of the Ordinary Members of Council who have been in office for the next longest period.

17. If, by reason of any Ordinary Member of Council, or any two or more Ordinary Members of Council, having been nominated for election to the office of President, or to that of Vice-President, the number of Ordinary Members of Council to be elected at the ensuing Annual General Meeting shall be greater than four: the Council shall nominate the number in excess of four of the persons to be submitted to that Annual General Meeting for election as Ordinary Members of Council, and four shall be nominated as provided by Bye-laws 18 and 19.

18. At least two months before the date of each Annual General Meeting, the Council shall issue to each Member of the Society a list of the Council, showing which of its Members are to retire at the date of that meeting, and giving the names of the persons who have been nominated by the Council for election at that meeting to the office of Vice-President, and also the names of the persons, if any, who have been nominated by the Council under Bye-law 17 for election to the office of Ordinary Member of Council, and inviting nominations to the four of the vacancies about to occur, persons to fill which have not been nominated by the Council. Such nominations must be made upon a printed form, which will be supplied to any Member of the Society at his request, addressed to the General Secretary, and which form shall be as follows:—

SOCIETY OF CHEMICAL INDUSTRY.

*We, the undersigned Members of this Society, do hereby propose.....
 of in the County of
 as a candidate for election as a Member of Council of the
 Society, and I, the said.....am willing to stand for election, and
 if elected will endeavour to attend the Council Meetings, and do all in my power to
 promote the welfare of the Society.*

(SIGNED)

1.....	16.....

14.....	29.....
15.....	30.....

No such nomination shall be valid unless it be signed by at least ten Members of the Society, who are not in arrear with their subscriptions, nor unless it be received by the General Secretary, at the Society's Office, at least one month before the date of the commencement of the Annual General Meeting, to the election to take place at which it refers. Nor shall any such nomination be valid if the person nominated be ineligible for election under Bye-law 12 or Bye-law 15. No Member shall sign more than one Nomination Form.

19. If the number of persons nominated, as provided by Bye-law 18, be fewer than four, the further number necessary shall be nominated by the Council.

20. A complete List of the Council, showing which of its Members will retire at the forthcoming Annual General Meeting, and the names of all persons who have been nominated for election at that meeting, shall be printed as a Ballot List, and this Ballot List shall be sent to each Member of the Society at least five days before the commencement of the said Meeting.

21. On the first day of the said Meeting, at such stage of its proceedings as shall be most convenient, the Members present shall hand their Ballot Lists to the General Secretary, or, in his absence, to such other person as the President may appoint. Members unable to attend the Meeting may send their Ballot Lists before the Meeting to the General Secretary in sealed envelopes. Each such sealed envelope must be marked BALLOT LIST, and must, moreover, have written upon it the name of the Member sending it. The names written upon such sealed envelope having been compared with the Society's Register by the General Secretary, such sealed envelopes shall be opened at the Meeting by Scrutators appointed by the Meeting. The Scrutators shall see that the conditions of the ballot are strictly fulfilled.

22. Any Member shall be at liberty to strike out any name or names of Ordinary Members of Council printed on his voting paper, provided that the names so struck out are those in excess of the number of vacancies to be filled up.

23. If the office of President should become vacant by death or resignation during the period intervening between two Annual General Meetings, a new President shall be elected by the Council.

24. If any other vacancy shall occur in the Council during the period intervening between two Annual General Meetings, the Council shall elect a person to fill it until the next Annual General Meeting, when the Member who has been so elected by the Council shall retire, in addition to those who retire under Bye-laws 12 and 15. Such Member, however, shall be eligible for re-election, and shall be nominated for re-election at the Annual General Meeting next following his election by the Council.

MEMBERS AND THEIR CONTRIBUTIONS.

25. Every Candidate for admission as a Member of the Society must be proposed according to the form set out in Rule 26. He must be proposed by one or more Members to whom he is known personally. The proposal form must be sent duly signed to the General Secretary, who shall lay the same before the Council at its next Meeting. If the majority of the Members of Council present are in favour of his election, the Candidate shall be declared duly elected, and his name shall be entered in the Register of the Society. At whatever period of the year a new Member may be elected, he shall be required (unless the Council shall determine otherwise) to pay his subscription for that year; having done which he shall be entitled to receive all the numbers of the Society's Journal for that year.

26. The Nomination Paper must take the following form, and may be obtained from the General Secretary, or from any of the Secretaries of Local Sections :—

THE SOCIETY OF CHEMICAL INDUSTRY.

(Candidate's Name in full)
is hereby proposed as a fit and proper person to become a Member of the Society
of Chemical Industry.

For Names only of }
Members recommend- }
ing the Candidate. }

Signature of Candidate.....

Address to which the }
Candidate wishes the }
Society's publications }
to be sent, and which }
is to be entered in the }
Society's Register. }

Profession or Business }
Occupation. }

Date.....

27. Each Member shall pay an annual subscription of Twenty-five Shillings, due on the First of January in each year; but any Member may pay a life composition fee of Fifteen Pounds in lieu of an annual subscription.

28. A List of the Members of the Society, with their addresses, shall be printed and distributed to each Member of the Society in the month of January in each year.

29. No person shall be entitled to the privileges of Membership who is in arrear with his subscription. No Member whose subscription has not been paid shall be entitled to attend Meetings or to vote, or to receive gratuitously any of the publications of the Society; and if the subscription be not paid within four months after further application from the Secretary, due notice shall be given to the Member, whereupon his name shall be struck off the Register; he shall cease to have any right, privilege, or interest in the Society, and the arrears of subscription shall be recovered at law.

30. Any Member may withdraw from the Society at the end of any year, after giving notice to the General Secretary of his desire to withdraw, such notice to be accompanied by the payment of all arrears, if any, which may be due from him to the Society up to that date, and by such notice and payment he shall be released from all further liability as a Member.

MEETINGS.

31. The Council shall meet periodically, to examine accounts, to authorise payments, to act as a Committee of Finance, and to transact such business as may be necessary. Its meetings shall be convened by circular posted to all its Members, either by the order of the Council itself, given at a previous meeting, or by instruction from the President; and at any Meeting of the Council thus duly convened five Members shall constitute a quorum. The circular convening each Meeting shall be accompanied by an agenda paper, stating the nature of the business to transact which the Meeting is called, and also by a list of candidates for membership, if any, who are to be proposed for election at such Meeting, with the address and occupation of each such Candidate.

32. For the furtherance of the objects of the Society, for advice, examination of and reports upon novelties, improvements, inventions, processes, or other matters of interest in connection with the chemical industries, the Council may appoint Special Committees, which may consist in part or entirely of persons other than Members of the Council. Such persons must be Members of the Society, and all Special Committees shall be under the control of the Council. The President for the year shall be the Chairman of all Special Committees, and the General Secretary of the Society shall be the Secretary of them, unless otherwise arranged by the Council.

33. No Special Committee, nor any Committee of Local Section shall have any control over the funds of the Society, except to the extent to which funds for its use may be voted by the Council. An account of the manner in which any funds so voted for the use of any Committee have been expended shall be furnished to the Council on or before the 31st of December in each year.

34. An Annual General Meeting of the Members of the Society shall be held at such time and place as shall have been decided at the previous Annual General Meeting, to receive a Report from the Council, to elect office-bearers, to hear an address by the President, and to transact such other business as may be necessary or desirable, including, if the Council think fit, the reading and discussion of papers.

35. Notice of each Annual General Meeting shall be given in the Journal of the Society at least fourteen days before the day on which such Meeting is to commence.

36. The order of the business to be transacted at the Annual General Meetings shall be decided by the Council from time to time.

37. A Member may introduce one visitor at any General or Local Meeting of the Society. Such visitor may, by leave of the Chairman, take part in any discussion, but he shall not vote.

38. The Council may accept communications from gentlemen not Members of the Society, and allow them to be read before the Members.

MISCELLANEOUS.

39. If any person proposed to the Council for election as a Member of the Society be rejected, no record of his rejection shall be placed upon the minutes.

40. All papers proposed to be read before a General Meeting of the Society must be sent to the General Secretary fourteen days at least before the date of that Meeting. The Council shall allow them to be read or ask that they be amended, or reject them, as it thinks fit.

41. The Society shall have the right of priority of publication for three months of all communications made to the Society.

42. A Journal of the Society shall be published at least once a month, and shall be distributed gratuitously to the Members of the Society, except that no Member of the Society shall be entitled to receive it who has not paid his subscription.

43. The author of any communication which has been read before the Society or before any of its Local Sections, and the publication of which in the Society's Journal has been authorised by the Council, may receive not more than fifty copies of such communication, together with the discussion thereon, if the author desires it, printed separately, provided that he gives notice of his desire to receive such copies upon the manuscript of his communication forwarded by him to the Editor of the Journal.

44. The Journal of the Society shall be edited and managed as the Council shall prescribe from time to time. Nothing shall appear in it, the publication of which has not been authorised by the Council, or by a Publication Committee appointed by the Council. It shall contain, in full or in abstract, as the Council may in each case decide, such of the communications read before the Society or any of its Local Sections as the Council may consider it desirable to publish, together with such other matter, relating to applied chemistry and the practice thereof, as the Council may from time to time direct.

LOCAL SECTIONS.

45. Upon receiving a requisition signed by at least thirty Members of the Society from any particular district, the Council shall consider the advisability of allowing a Local Section for that district to be formed.

46. Each Local Section may make rules for its own government, but no such rules shall be valid unless and until they have been sanctioned by the Council of the Society, and such rules must in each case include the following provisions :—

(a) That the affairs of the Section shall be conducted by a Committee, which shall be elected by the Members of the Section, in such manner as the rules of the Section shall provide.

(b) That, except elections to fill up unforeseen vacancies, all elections to the Committee of a Local Section, and all election of Officers of the Section, whether such Officers be appointed by the Committee or otherwise, shall take place in the month of April, and that the names of the persons elected shall in each case be reported to the Council on or before the 20th of that month; but that the Members of Committee and the Officers thus elected or appointed in April shall not take office, and those whom they are to succeed shall not retire from office, in each case until the close of the session then current.

(c) That no modification of or addition to the rules of the Section shall be made without the consent of the Council of the Society.

47. When the Council has consented to the formation of a Local Section of the Society, and has approved the rules by which it is proposed that that Section shall be governed, the Chairman and Honorary Secretary of that Section shall be *ex-officio* Members of the Council of the Society.

48. Each Local Section shall be bound to defray its own expenses for printing, stationery, advertising, postage, reporting, and hire of rooms; but the Council shall make a grant in aid thereof out of the General Funds of the Society, or may, if it think fit, defray the whole thereof.

49. An account of the expenditure of each Local Section during the preceding twelve months shall be furnished to the Council on or before the 15th of June in each year.

50. Except for printing, stationery, advertising, reporting, postage, and hire of rooms, no Local Section shall incur any expense without having previously obtained the sanction of the Council thereto.

51. For the purpose of meeting its expenses, each Local Section may require its Members to pay a Sectional subscription, which, however, shall not exceed Five Shillings per annum.

52. Every Member of the Society shall be entitled to attend, and to take part in the proceedings of the meetings of all Local Sections, except meetings concerning the business management of any Section of which he is not a Member.

53. The Committees of Local Sections shall have power to accept or reject communications proposed to be read before such Sections.

ALTERATION OF THE BYE-LAWS.

54. Any Member of the Council may submit to the Council in writing any proposal to alter or add to the present Bye-laws, and the Council may submit such proposal to the ensuing Annual General Meeting, if it think fit; but the Council shall submit such proposal to such Annual General Meeting, on a requisition to that effect, signed by at least Twenty Members of the Society, who are not in arrear with their subscriptions, provided that no proposed alterations of, or additions to the Bye-laws shall be considered at any Annual General Meeting, unless at least one month's notice thereof has been posted to every Member of the Society.

EXTRAORDINARY MEETINGS.

55. Extraordinary General Meetings of the Society may be convened at any time by the President and Council, or on receipt of a written requisition, signed by at least Thirty Members of the Society. The circular calling the Meeting must state the objects thereof, and must be delivered or sent by post to each Member of the Society at least fourteen days before the proposed Meeting is to take place.

THE JOURNAL OF THE Society of Chemical Industry:

A MONTHLY RECORD

FOR ALL INTERESTED IN CHEMICAL MANUFACTURES.

No. 1.—VOL. V.

JANUARY 29, 1886.

Non-Members 30/- per annum; Members
21/- per Set; Single Copies 2 6.

The Society of Chemical Industry.

Past Presidents:

Sir H. E. Roscoe, M.P., LL.D., V.P.R.S.	1881—1882.
Sir Frederick Abel, C.B., D.C.L., F.R.S.	1882—1883.
Walter Weldon, F.R.S.	1883—1884.
W. H. Perkin, Ph.D., F.R.S.	1884—1885.

COUNCIL FOR YEAR ENDING JULY, 1886.

President: E. K. Mnspratt.

Vice-Presidents:

Sir F. A. Abel, C.B., D.C.L., F.R.S.	Peter Griess, Ph.D., F.R.S.
Sir I. Lowthian Bell, Bart., F.R.S.	W. H. Perkin, Ph.D., F.R.S.
Alexander M. Chance.	Sir H. E. Roscoe, M.P., LL.D., V.P.R.S.
Prof. James Dewar, F.R.S.	John Spiller.
James Duncan.	E. C. C. Stanford.
David Gamble.	J. C. Stevenson, M.P.

Ordinary Members of Council:

R. Forbes Carpenter.	S. A. Sadler, Ph.D.
Henry Doulton.	Sir Bernhard Samuelson, Bart., M.P.
John Evans, D.C.L., F.R.S.	Sir Chas. Tennant, Bart., M.P.
Ivan Levinstein.	Prof. W. A. Tilden, F.R.S.
Rudolph Messel, Ph.D.	John Williams.
B. E. R. Newlands.	
Thomas Royle.	

With Sixteen Chairmen and Secretaries of Sections.

Honorary Treasurer:

E. Rider Cook, M.P., East London Soapworks, Bow, E.

Honorary Foreign Secretary:

Ludwig Mond, 20, Avenue Road, Regent's Park, N.W.

General Secretary: Charles G. Cresswell.

Offices:

Palace Chambers, 9, Bridge Street, Westminster, S.W.

NOTICE.

The supply of copies of the Journal for January, 1882, being now exhausted, the Secretary would be glad to receive communications from members possessing extra copies of that number, in good condition, with a view to purchase.

Should sufficient applications for complete sets be received, the number will be reprinted.

CHANGES OF ADDRESS.

G. M. Allender, 1/o Rochampton; Stammerham, Horsham, Sussex.
J. B. Binks, 1/o Esk Street; 1, Criffel Street, Silloth, Cumberland.
T. Lynton Briggs, 1/o Fulham; c/o Read, Holliday & Sons, Huddersfield.
A. Crum, 1/o Kelburne; Thornliebank, Glasgow.
L. C. Daniell, 10, Swan Lane, Upper Thames Street, London, E.C.
Chas. Davis, 1/o Roman Road; 10, Oakfield Cottages, Oakfield Road, East Ham, E.
T. R. Duggan, 1/o Stoke Newington; 32, Narford Road, Upper Clapton, E.
Percy F. Frankland, Grove House, Pembroke Square, W.
C. N. Hake, 1/o Chelsea; 14, Great Smith Street, Westminster, S.W.
W. F. Henderson, 1/o Leazes Terrace; Moorfield, Claremont Gardens, Newcastle-on-Tyne.
T. Hughes, 1/o Lower Gornal; Public Analyst's Laboratory, West Wharf, Cardiff.
N. H. Humphrys, Gas Works, Salisbury.
G. H. Hurst, 1/o Cable Street; 22, Blackfriars Street, Salford.
W. H. R. Kerry, 1/o Seacombe; Laboratory, 14 Castle Street, Liverpool.
W. Jesse Lovett, 1/o Market Street; Alverthorpe Road, Wakefield.
J. G. F. Lowson, 1/o Balthayock; St. Leonard's Mill, Lasswade, Midlothian, N.B.
R. S. Marsden, 1/o Sheffield; Rillington, York.
T. S. Marsh, 1/o Seacombe; Ash Lea, Litherland Park, Liverpool.
Wm. Marshall, 1/o Radelyffe; 79, Blue Bell Hill, Nottingham.
R. M. Morrison, 1/o Edinburgh; The Poplars, Beulah Hill, Upper Norwood, S.E.

Jas. Murrie, 1/o Kinning Park; 206, Gallowgate, Glasgow.
F. W. Renaud, 1/o Burstow; 65, Radpole Road, Fulham Road, S.W.; and 19, Great George Street, Westminster, S.W.
J. H. Richardson, 1/o Runcorn; 233, Blackburn Road, Accrington.

W. Wightwick Roberts, 1/o South Kensington; Oficina de Ensayos, Valparaiso, Chili.

A. E. Robinson, 1/o Bull Ring; Faraday Chemical Works, 5 and 6, Aston Road, Birmingham.

W. J. Rowley, 1/o Manchester; Wellington Villas, Wellington Road, Handsworth, Birmingham.

C. A. Smith, 1/o Billiter Square; The Laboratory, 8, Loftus Street, Sydney, New South Wales.

A. Spiegel, 1/o Hochst-am-Main; Messel, bei Darmstadt.

H. E. Stevenson, 2, Bromfield Gardens, Onslow Road, Richmond, Surrey.

Wm. Stevenson, 1/o Addle Hill; Standard Works, 95A, Southwark Street, London, S.E.

A. Trobridge, 1/o Smethwick; 6, Willow Avenue, Sandon Road, Edgbaston, Birmingham.

A. W. Warrington, 1A, Nikolausberger Weg, Gottingen, Hanover.

P. J. Winsor, 1/o Bank Quay; c/o Lever Bros., Soap Works, Warrington.

CHANGES OF ADDRESS REQUIRED.

W. Arthur, 1/o Ring's End, Dublin.

F. Giesbers, 1/o King's Road, St. Pancras.

W. A. Meadows, 1/o Rainhill.

H. Peile, 1/o Middleton one Row, near Darlington.

J. Robinson, 1/o Devon Square, Newton Abbott.

S. Studer, 1/o Warrington.

J. H. Wildsmith, 1/o Upper Kennington Lane.

LIST OF MEMBERS ELECTED, JANUARY 22nd, 1886.

Walter S. Allen, 13, Beacon Street, Boston, U.S.A., clerk to State Board of Gas Commissioners.

G. H. Allison, Sea View, Litherland Park, near Liverpool, analyst.

Aug. Arcemis, 43, Paseo de las Acacias, Madrid, professor.

T. E. Ash, 8, Deanery Road, Romford Road, E., manufacturing chemist.

J. C. Belcher, 19, Charles Street, Marine Parade, Brighton, analyst.

Wm. Bogle, Wappinger's Falls, Dutchess Co., N.Y., U.S.A., superintendent of printworks.

Wm. Bracewell, Brinscall, near Chorley, bleacher's engineer.

C. F. Burgmann, Burry Port, Carm., South Wales, white lead manufacturer.

W. C. Carter, 2, Weech Road, Burgess Hill, Hampstead, N.W., student.

Peter Cowell, Free Public Library, Liverpool, librarian.

T. B. Cussen, Lenton, Nottingham, Inland Revenue officer.

J. F. Davis, M.D., 245, West 11th Street, New York, U.S.A., physician.

Freo Lal Dey, 4, Beadon Street, Calcutta, manufacturing chemist.

Geo. Donald, Lennox Mill, Campsie, N.B., printworks chemist.

F. Ermen, jun., Nassau Mills, Patricroft, Manchester, dyer and bleacher.

W. F. A. Gausson, 53, Eaton Square, S.W.

Edmund, The Vinery, Burton Joyce, Notts, lace manufacturer.

A. F. Jones, South Arthurlie, Barrhead, Glasgow, printworks manager.

F. W. Knox, Colonial Sugar Refining Co., Sydney, N.S.W.; and c/o F. Parbury & Co., 7, East India Avenue, Leadenhall Street, E.C.

A. D. Markham, 43, Trinity Square, Borough, S.E., pharmacist.

Stephen W. Mitchell, Craigbank, Giffnock, Thornliebank, N.B., analyst.

Teikichi Nakamura, Japanese Legation, 9 Cavendish Square, W., assistant professor.

Wm. R. Nichols, Mass. Inst. of Technology, Boston, U.S.A., professor of chemistry.

Lewis M. Norton, Mass. Inst. of Technology, Boston, U.S.A., professor of industrial chemistry.

J. R. Pedler, Woodbank, Lordship Lane, Dulwich, S.E., clerk.

Robert Riddell, 1/o Messrs. Ailsopp, New Brewery, Burton-on-Trent, brewer.

Thomas Rowley, 9, Conyngham Road, Victoria Park, Manchester, expert on indiarubber.

James Russell, Parkhead Cottage, Carlisle, N.B., iron-founder.

Frank P. Siddall, Averley Villa, Station Road, New Barnet, analyst.

Alfred Smith, Bank Lane Chemical Works, Clayton, Manchester, drysalter.

A. A. Tunbridge, The Crescent, King Street, Leicester, student at gas-works.

George Walker, City Analyst's Laboratory, 138, Bath Street, Glasgow, chemist.

R. Walker, The Pallett, Quarlton, near Bolton, calico printer.

Samuel G. Webb, 38, Montpelier Road, Peckham, S.E., chemical student.

George Wilton, Gasworks, Silvertown, E., tar distiller.

John Wilson, Redheugh Chemical Works, Gateshead-on-Tyne, chemist.

Robert B. Wood, Dalquhurn Works, Renton, N.B., chemist.

Deaths.

Thos. Balmer, Halewood, near Liverpool.

C. Felce Hare, 23, Beaufort Road, Clifton, Bristol.

T. Sinister Johnson, 5 Holyrood Terrace, Malvern.

J. Zublin, Offenbach-am-Main.

London Section.

CHEMICAL SOCIETY'S ROOMS, BURLINGTON HOUSE.

Chairman: David Howard.

Committee:

Sir F. A. Abel.

H. E. Armstrong.

W. Lant Carpenter.

W. Crowder.

C. Graham.

S. Hall.

A. K. Huntington.

R. Messel.

B. E. It. Newlands.

B. Redwood.

T. Royle.

Local Sec. and Treasurer: Thos. Tyrer,
Garden Wharf, Church Road, Battersea, S.W.

MEETINGS, SESSION 1885-86.—First Monday in each month (unless otherwise indicated).

ORDINARY MEETINGS.

First Monday in the Month, at 8 p.m.

February 1.—Mr. Gustav Bischof—"Notes on Dr. Koch's Water Test." Mr. J. W. Westmorland, A.R.S.M.—"The Estimation and Valuation of Copper Ores and Products for Commercial Purposes."

March 1.—Mr. Boyerton Redwood, F.I.C.—"Viscosimetry." Mr. T. B. Lightfoot, M.I.C.E., M.I.M.E.—"Ice Making and Cooling Machinery."

April 5.—Professor Unwin, M.I.C.E.—"The Principles and Methods of Testing Cementing Materials." This meeting will be held in the Central Institute, City and Guilds of London Institute, Exhibition Road, South Kensington.

May 3.—Mr. A. G. Salamon—"Purification of Water." Messrs. Macnab and Beckett—"The Treatment of Water for Technical Purposes."

June 7.—Dr. Meymott Tidy—"Chemical Treatment of Sewage."

July.—Annual Meeting at Liverpool.
Notices of papers and communications for the meetings to be sent to the Local Secretary.

Meeting held Monday, January 4, 1885.

MR. D. HOWARD IN THE CHAIR.

ON THE ENRICHMENT OF COAL-GAS BY CERTAIN HYDROCARBONS.

BY GEORGE E. DAVIS.

EVER since the introduction of illumination by means of coal-gas, various processes have been put forward and patented, having for their object the enrichment of the gas with certain hydrocarbons. One by one have these processes appeared, and as certainly have they disappeared, so that there remains but the bare record of their existence, and, strange to say, there does not appear, in the literature devoted to the subject, any rational ideas of the why and wherefore of the failures of the different processes which have been from time to time devised.

If we go back to the earliest records of gas-lighting, we shall find that the tar produced in the operation of the manufacture of gas proved in those days to be an article very difficult of sale, and many efforts of a

crude nature were made to turn it into gas. In a pamphlet published by Mr. Clegg in 1820, a circular oven was described for carbonising coal, in which a pipe was fixed near to the mouth of the oven, so contrived that the tar, as it was condensed, returned upon trays, and was thereupon converted into gas. Mr. John Grafton (a pupil of Mr. Clegg's), about this time also sought to convert the tar into gas, and in one of his patented settings the retorts were placed in an inclined position, and a secondary retort added for the purpose of receiving the tar and converting it into gas. This idea was never probably worked at with a view of enriching ordinary coal-gas, but was most likely adopted as a means of getting rid of a very noxious and inconvenient by-product, for in those days the expedient of utilising it as fuel was not thought of.

Supposing for a moment that these crude attempts, and others of a similar nature which followed them, had been successful in the matter of gas making, pure and simple, it is doubtful how far they would have conduced to the enrichment of the gas, as I have found by experiment that the pitch which constitutes about three-fifths of the total weight of the tar produces a gas absolutely devoid of illuminating power, in quantity about 25 per cent. of its weight, and the accumulation of naphthalin and of heavy oils in the process would militate against successful working.

At an early date, however, many processes were devised by Ibbotson, Donovan, Selligie, Sanders, Manby, Val Marino, White and others, having the idea in view to enrich ordinary coal-gas with the vapours of certain hydrocarbons, or to impregnate non-illuminating gases with these vapours so that the resulting gas might be used for purposes of illumination. All these processes have sunk into oblivion in this country, for one very good commercial reason,—there is no cheaper raw material than coal upon which to operate, nor is there any other substance extant which will give as a basis, by simple destructive distillation, ten thousand cubic feet of gas per ton of coal, of an illuminating power equal to seventeen candles, at the same price as coal.

In many places seventeen candles' illuminating power is all that is required, and when an Act of Parliament stipulates for more than this, coal again, of a richer quality, in the shape of cannel, is almost universally employed. Any substance, then, for enriching gas, must be able to compete financially with cannel coal.

But supposing we are satisfied with the gas first, I believe, devised by Mr. C. Ibbotson, in 1826, produced by passing steam through red-hot coke, the question is whether it is possible to impregnate such a gas with the vapours of volatile liquids more perfectly and more cheaply than can be done during the process of manufacturing ordinary coal-gas in the usual manner. I think the able paper of Mr. Lewis T. Wright, read before the Manchester Section of this Society, on December 4th, 1883, answers this question in the direct negative. To attempt the carburation of gas by employing any compound of the benzene series seems to me the height of absurdity, seeing that it is from coal-tar that these products are produced, and the cost of extraction must be added to the original cost of the tar. If these compounds are to be used at all, it is the crude tar which should be operated upon in the gas-works, the tar being made to replace cannel.

In 1832, Lowe introduced his system of naphthalising gas specially devised for enriching a poor coal-gas, in order to make it equal in illuminating power to that produced from cannel coal. The original idea was to use the wet gas-meter as the carburetter, filling

it with the light spirit obtained from coal-tar; but it was soon found to be too costly, to require too much attention, and altogether unsuited for universal application. The principle here advocated by Mr. Lowe has been the favoured ground for inventors for many years, but I hope to show the apparent impossibility of its practical attainment, under present circumstances at any rate.

If inventors, however, have been discouraged by the high and varying prices of volatile members of the benzene series of hydrocarbons, those of the paraffin series (extracted from American petroleum) have been open to them, yet with gasoline at sixpence half-penny per gallon, it is very doubtful whether this method would be able to hold its own financially against enrichment by cannel in the usual way. In many places, both for public and private lighting, the system of carburetting gas by impregnating it with the vapours of hydrocarbons has been in use over long periods, and from the experience gained, it has come to be a recognised fact that, if carburetting is practised at all, it must either be effected at the burner itself, or, if the gas is carburetted at the gas-works, it must undergo some special treatment in order to make the illuminants carry to the end of their destination.

Carburetting at the burners with liquid hydrocarbons does not, I think, require serious consideration, although I am told it is in operation in the corridors of the Manchester Exchange, and also at the St. Pancras Station in this city. The replenishing of the reservoir with liquid for each burner would certainly not be practised for long in any domestic establishment, and for any service of public lighting the method would not be likely to find favour with the attendants on account of the extra work it would entail. The liquid used in the two places already cited is good fluid creosote oil, and this at twopence per gallon is economical. In order to enable the benzene series of hydrocarbons to be used for carburetting, coal-tar would have to be reckoned as of no value whatever, and, indeed, with the present price of 90's benzol—viz., 1s. 11d. per gallon—it is very certain that many gas-works would do better by using the tar as fuel for heating the retorts or for carburetting the gas, than by selling it; there are indications now of it being used as fuel in some quarters. Properly applied as a fuel, one cwt. of coal-tar will do as much work as two cwt. of coke; so that there is not much chance of seeing benzol at such a price as will enable it to be used for carburetting.

When a gas is carburetted at the works (as, for instance, in America, where water-gas is made on the large scale), the mixture of carbonic oxide and hydrogen, after saturation with the hydrocarbon vapours, is passed through heated retorts, to "fix the carbon," as it is termed, as petroleum spirit is commonly supposed to possess less "carrying power" than the illuminants of ordinary coal-gas. There is no doubt that the process of heating does "fix the carbon"; but the reason must be sought in another direction than that usually indicated. The following table shows the vapour tensions of pure benzene and of gasoline, and it would appear, therefore, that the latter should have much more carrying power than the former:—

Deg. Cent.	Pure Benzene.	Gasoline.
-10°	13.4	43.5
0	26.6	81.0
+10	46.6	132.0
20	76.3	203.0
40	182.0	301.8

In cases of this kind, however, we must also remember that the nature of the gas itself into which the vapour diffuses exercises a very decided action upon the rate of evaporation. Coal-gas is more active

than air, in the proportion of 1.5 : 1; whilst hydrogen is nearly 3.5 times as active as air; so that, in practice, an apparatus for carburetting air would have to be of 3.5 larger capacity than one for carburetting a similar volume of hydrogen in a given time.

In order to be in a position to follow the experiments described farther on, and to judge of the feasibility of carburetting various gases with the vapours of volatile liquids, it will be as well to cast a glance at the composition of coal-gas generally. It must not be supposed that gas from coal possesses any exact composition. The proportions of its constituents are, however, fairly uniform; and it may be taken for granted that, when made from a good quality of ordinary gas-coal, it will contain about forty-six per cent. of hydrogen and thirty-four per cent. of methane (marsh gas), with about eight per cent. of carbonic oxide, and small quantities of nitrogen and carbonic acid. This is the vehicle or "carrier," and is permeated by those vapours of hydrocarbons which give it its illuminating power. These illuminants were generally stated as consisting almost entirely of olefiant gas; and, later, of benzene, propylene, and ethylene. In several recent analyses, the last-named gas is stated to occur to the extent of 2.5 per cent. by volume. Whether or not this is correct demands further investigation; but I am inclined to think there is much less ethylene in coal-gas than is usually stated, and in some varieties of gas it is doubtful whether it exists at all. With regard to the aromatic series of hydrocarbons, it is certain that these illuminants in coal-gas do not consist of benzene simply with a vapour tension equal to that shown in the foregoing table. They consist of the vapours of hydrocarbons boiling below the point of ebullition of pure benzene itself to that of pseudocumene and mesitylene, or from 80° C. to 160° C. and the vapour tension of this mixture of hydrocarbons is far less than that of benzene itself; so that ordinary coal-gas is much more nearly saturated with vapours than most persons imagine.

The vapours of the volatile hydrocarbons present in coal-gas may be easily extracted by passing the gas through olive oil; the liquid hydrocarbons being displaced and collected by blowing steam through the saturated oil. It is possible by these means to extract from three to four gallons of liquid hydrocarbons from 10,000 cubic feet of ordinary coal-gas, according to the temperature employed; the illuminating power of the gas being reduced accordingly. In order to ascertain the composition of the vapours made at medium and high temperatures, I passed a large quantity of gas through olive oil, regained the liquid hydrocarbons, and separated them roughly by means of Le Bel and Heninger's fractioning tubes with the following results:—

	Medium Heats. High Heats.	
Hydrocarbons extracted	gallons 4	3.2
Illuminating power of gas before extraction.....	candles 19	17
Do. do. after extraction ..	" 8	8

Boiling Point of Hydrocarbons.	Per cent.	Per cent.
Below 80° C.	2.0	1.2
80—83	53.0	50.1
90—100	3.6	2.5
108—113	21.0	27.9
116—128	3.2	2.1
135—140	8.1	11.2
145—150	2.0	2.0
150—160	3.3	1.7
Above 160	3.8	1.3
	100.0	100.0

Cannel gas, having an illuminating power of twenty-seven candles, was also passed through olive oil, with the result of obtaining only 2.9 gallons of liquid

hydrocarbons; reducing the illuminating power of the gas to nineteen candles. This liquid distilled as follows:—

	Per cent.		Per cent.
Below 23° C.	12.0	90—100° C.	8.3
30—35	1.5	100—108	4.0
35—73	5.2	108—113	7.1
73—78	11.2	116—140	2.4
80—83	41.0	140—160	0.8
85—90	5.0	Above 160	1.5

It will be seen from the above that the nature of the hydrocarbon vapours present in cannel gas is substantially different from those in coal-gas. The vapours given off below 23° C. required condensation in ice and salt, and were doubtless those of crotonylene. They were brominated, and the bromo compound further examined.

These experiments seem to point to the fact that if it is desired to increase the illuminating power of coal-gas to that of cannel, the benzene series of hydrocarbons must not be exclusively employed. A certain amount of them may be necessary; but to do it in the way ordinarily proposed would be ruinous in cost. Experiment has shown that the extraction of one gallon of liquid from 10,000 cubic feet of the gas reduces the illuminating power about three candles; so it is fair to presume that the addition of one gallon will increase it by that amount. Every three candles (if carburetted with 90% benzol—the lowest quality permissible) would, therefore, cost 1s. 8d. per 10,000 cubic feet. But I shall presently show that this is only a mythical figure, as a reaction takes place (not observed before, I believe) which militates against the success of any process of carburation which depends upon the vapourisation of a heterogeneous fluid by the passage of a mixed gas through it, already nearly saturated with vapours of varying vapour tension.

In processes of carburation by the above system, a good "solvent naphtha" has been the usual substance employed. Dr. Letheby's specification for carburetting naphtha stipulated for a quality distilling seventy per cent. at 130° C., and ninety per cent. at 150° C. I have made many experiments with naphtha of this quality, and find that, at a temperature of 20° C., 10,000 cubic feet may be made to absorb and exchange about 3.25 gallons of the light portion, and after a little while scarcely anything is vapourised. With 50/90 benzol, at 20° C., 10,000 cubic feet will take up about 7.75 gallons, and at 15° C. about four gallons of the lighter portions; while with ninety per cent. benzol, at 20° C., 10,000 cubic feet will absorb and exchange about fifteen gallons. Were it not for the ruinous cost of ninety per cent. benzol for such a process, no doubt it might be successfully applied, now that we know more about the principles which govern carburation, and provided a market could be found, at a reasonable price, for the less volatile portion.

In the experiments just quoted, the apparatus was fed plentifully with the various carburetting agents; but experience soon showed that the quantity taken up became less and less as the benzene evaporated—50/90 benzol testing fifty per cent. at 100° C., and ninety-two per cent., at 120° C. after being evaporated to about one-third tested, the first drop distilled at 103° C., twenty-four per cent. at 110° C., and fifty-six per cent. at 120° C. Solvent naphtha, which showed on distillation thirty-five per cent. at 120° C., seventy per cent. at 130° C., and ninety per cent. at 150° C., yielded after passage of the gas (during which only 1-16th of the liquid had evaporated) twenty-eight per cent. at 130° C., and seventy-nine per cent. at 150° C. With ninety per cent. benzol, which tested ninety-one per cent. at 100° C., and a dry flask at 118° C., a residue was left when

only one-fourth of the liquid had evaporated, testing seventy-nine per cent. at 100° C., and ninety-two per cent. at 120° C. I found also that this happens when gasoline is employed as the carburetting agent. A great deal of this information (but without quantities being given) has been recorded by older observers. Hughes, in his "Treatise on Gas Works," states:—"The main difficulty existing against the carburisation of gas is the irregular evaporation of the fluid; a portion of which, when placed in the carburating vessel, is remarkably volatile, and passes off in abundance, requiring burners with very small holes to prevent the formation of smoke. By degrees, when the most volatile vapours have evaporated (the gas, in consequence, not being enriched), a difficulty arises from the smallness of the burners."

Carrying the above investigation further, I found that the residual spirit from carburetting contained in absolute quantities more toluene, xylene, pseudocumene, and mesitylene than entered into the composition of the original fluid. The only way in which I could account for this was by supposing that the gas, in taking up benzene vapour, had deposited the heavier hydrocarbons of less vapour tension to make room for it. This surmise was found to be correct. I passed a large quantity of seventeen-candle gas through pure benzene (boiling between 80.5° C. and 80.8° C.), until the volume of the carburetting fluid was reduced to one-fifth. The residual spirit now distilled only eighty per cent. at 100° C., and ninety-three per cent. at 120° C., proving beyond doubt that toluene, xylene, and the higher hydrocarbons, had been deposited from the gas. I carried out the same experiment with gasoline, and found that the aromatic hydrocarbons were also deposited amongst the residual fluid to quite as great an extent as when using ninety per cent. benzol as the carburetting fluid. Of course, it would be possible to contrive a carburetting apparatus fed with a continuous stream of the enriching fluid, so that while ninety per cent. benzol was entering the apparatus, a constant outflow of toluene or solvent naphtha would take place. I have arranged a small apparatus on this plan; but the results obtained with it have assured me that the process would not be commercially successful. The late Mr. T. Collinge (with whom I have made many experiments), when chemist to the Air Gas Company, of London, found that 1200 cubic feet of air gas, when made of sixteen-candle power, contained the vapour of four gallons of gasoline, which is as near to the saturation point of a practical temperature as it is possible to work, as, if cooled to 0° C., some of the heavier hydrocarbons were sure to be deposited. I have come to the conclusion, also, that the vapours of the paraffin series of hydrocarbons have, volume for volume, or weight for weight, much less illuminating power than those of the aromatic series. The above experiment with air gas seems to point to this; but as the presence of air is found to interfere seriously with the illuminating power of coal-gas, it is only fair to assume that it would also injuriously affect the quality of the air gas, of which it constitutes ninety per cent. Mr. W. Lyon, however, has placed on record an experiment which would tend to prove the truth of my supposition. The experiment is given in detail in "King's Treatise on Coal-Gas," vol. iii. p. 355. A thousand feet of seventeen-candle coal-gas, by the absorption of 127 gallons of gasoline, became 1270 cubic feet of 38.83 illuminating power; or 2.5 candles produced in 1000 cubic feet by each gallon of the carburetting fluid. Compare this with the enrichment produced by the use of the benzene series: 1000 cubic feet of good coal-gas will give up 0.3 gallon of liquid hydrocarbons in losing about nine candles illuminating power, or three candles per

gallon per 10,000 cubic feet. I must confess I have never (at the ordinary temperature of 15.5° C.) been able to saturate coal-gas with as much gasoline as Mr. Lyon succeeded in doing. The utmost quantity I have succeeded in making 1000 cubic feet of coal-gas hold at 15.5° C. has been two gallons; so without doubt Mr. Lyon used a more volatile sample than I did, and it probably contained a less percentage of the heavier hydrocarbons. From these experiments it will be readily seen that carburisation in this way, even if it were practically possible, would never pay as a process of enrichment.

I do not think the subject of the mixing of vapours having very great differences of vapour tension has been studied sufficiently in connection with the manufacture of coal-gas. If it had, there would have been fewer attempts at carburisation in the direction already indicated; and other phenomena, seemingly inexplicable, would have been readily explained. In "King's Treatise on Coal-Gas" (*loc. cit.*), it is stated: "At Lowell, Massachusetts, the naphtha gas, after being measured, was passed into the hydraulic main of the coal-gas, with which it was washed and purified. The object of mixing the gases at this point is not clear, except it be with the idea of effecting a thorough amalgamation of the compound in the course of its subsequent treatment."

There is no doubt that by this method the illuminating power of the gas would be more permanent, in consequence of time and opportunity being given for the vapours of high tension to dislodge and occupy the place of those of low tension, and thus be able to withstand greater variations of temperature without the tendency to precipitate any illuminant in the liquid form.

It was not my intention at the outset to speak of any method of enrichment by means of solid hydrocarbons; but perhaps the method of carburisation known as the albo-carbon light deserves to be noticed. Upon ordinary gas-lights it may, perhaps, be difficult to assure a casual observer of the efficiency and economy of this principle; but with 9-candle gas there is no difficulty whatever. Most of you will be aware that at the Rockingham Gas Works, where my process for the extraction of benzene from the gas is in operation, the residual gas is quite unfit for purposes of illumination. After extracting about 4 gallons of liquid hydrocarbons per 10,000 cubic feet of the gas, this debenzolised gas has to be burnt from one of Bray's "market" burners in order to illuminate a room 10 feet square, and that not very satisfactorily. By employing the albo-carbon light, the illuminating power is with ease brought up to 20 candles, and the gas consumption reduced from 23 to about 3½ cubic feet per hour. I think the albo-carbon system deserving of great extension, though I am doubtful whether the average householder is sufficiently regardful of his purse to undergo the extra labour of charging the apparatus periodically with the necessary naphthalene.

I must now return to the subject mentioned in the early part of this paper—viz., the conversion of the tar into gas, and a method of using this gas for enriching the principal portion; as, if it could be effected satisfactorily, I believe it would bring a greater revenue to the gas companies than by selling the tar at such ridiculously low prices as some of them are at present obtaining. Tar is slowly but assuredly increasing in quantity, though means might be adopted in the gas-works whereby a large percentage might be curtailed. Low temperatures, with 9000 cubic feet of gas per ton, will yield, with some coals, 16 gallons of tar; whilst high temperatures will yield but 9 gallons, with about 11,000 cubic feet of gas. Now, if in every gas-works, they would in

this way curtail the supply of tar, they would be reducing the production of the United Kingdom by about 30 per cent., which would not fail to have an effect on prices, both of benzol and of pitch, which are now extremely low, and will not rise unless the supply of tar is diminished. Then, again, instead of selling tar, it can be made to replace the cannel coal, now almost universally employed for increasing the illuminating power of ordinary gas. I have already attempted to show that the gaseous illuminants of gas made from cannel coal are quite different to those existing in coal-gas; and coal-tar can, by proper treatment, be made as valuable to the gas maker as the best cannel coal.

In the early days of gas making, the attempts to gasify tar were of a very crude nature. It was run into retorts, there to be reheated, or on to trays placed inside them, with the result that every pipe and outlet became speedily choked with pitch. The nature of tar is now more completely understood, and some of us may be able to avoid the mistakes into which early operators fell. There are, in tar, three substances of no use to the manufacturer of gas intended for illuminating purposes—viz., pitch, naphthalene, and anthracene; and unless these are extracted before treatment, they become his *bêtes noires*. The process I am now about to advocate depends upon the elimination of these three products from the tar, and the conversion of the remainder into gas. The boiling point of anthracene is so high that the heat of the retorts has very little action upon it, unless the heat is raised too high; in which case viscid oils are produced, which tend to choke up the apparatus. Naphthalene is exceedingly difficult to deal with. It volatilises in a great measure, and chokes up the condenser and other cool portions of the apparatus; while another portion is changed into di-naphthyl and iso-dinaphthyl, which are of no use to the gas maker. Pitch, when carbonised, yields only about 25 per cent. of volatile matter, nearly entirely gas of no light-giving value whatever; and, of course, if this gas were mixed with that from the coal, it would much dilute its illuminating power.

It is well known that light oils from gas-tar, petroleum spirit, petroleum residues, creosote, heavy oils from gas-tar, etc., become gasified to a great extent by heating to redness, or by passing over red-hot surfaces, and about 80 cubic feet of 50-candle gas thereby obtained per gallon, possessing a specific gravity of '912, which, with oils weighing 10·8 lb. to the gallon, is equal to 16,600 cubic feet of 50-candle gas per ton. Now, this rich gas approaches more nearly the composition of rich cannel gas, than that made from any other substance. The greatest illumination is produced from the formation of very low-boiling hydrocarbons of great vapour tension, such as crotonylene (C_4H_6), which I have often separated in large quantities; and to these the illuminating power is principally due. Thorpe and Young (*Ann. Chem. Pharm.* clxv. 1) found that solid paraffin, by heating under pressure, is resolved into a mixture of liquid products consisting essentially of low-boiling paraffins, and medium and high-boiling paraffins and olefines; and there is but little doubt that some reaction or decomposition of this nature takes place when the vapours of the coal-tar oils are passed through a red-hot retort.

In order to carry out this process of enrichment upon a practical scale (say for works carbonising 50 tons of coal per day), a set of three 10-ton tar-stills would have to be provided, so that they might be worked in sequence, one always being run off and refilled.

The raw tar is distilled in the usual manner, and the distillate conveyed into three separate tanks, A,

B, and C; the still being stopped when a sample of the pitch, on being withdrawn, twists easily at a temperature of 55° C., and when thus made it is of an extremely good quality, and commands a ready sale. The contents of tank A will remain liquid, naphthalene will separate from tank B on cooling, and anthracene from tank C. If tank B is constructed in the form of a filter, the naphthalene can be easily removed from the process, and either worked up, sold, or used as fuel. The oils in tank C must be filter-pressed, to remove the anthracene; after which the contents of all are ready to be made into gas. When sufficient oils have accumulated, another of the stills is filled with a mixture from the tanks A and B, and the whole slowly distilled; the vapours being passed directly into one end of a through retort heated to dull redness, the gasified hydrocarbons passing out at the other end by means of the ascension pipe, and mixing with the gas from the ordinary retorts. When four-fifths of the contents of the still have been vaporised, the fire is withdrawn and the still filled up with raw tar, which is distilled as before, and the pitch run out for sale; after which, the still is again ready for vaporising another batch of oils. When sufficient filtrate from the anthracene has accumulated, it is distilled in whichever still happens to be at liberty. The first fourth is run to the creosote or B tank, the second fourth into the anthracene or C tank; the still being stopped when the pitch will just soften at 50° C., when it is run off into the pitch-house in the same manner as when dealing with ordinary tar. The whole process is so simple that any intelligent lad might work it. It does not depend upon any complicated chemical tests; a thermometer and a hydrometer being the only apparatus required. In this way every gas-works would be able to supply an illuminating gas of good quality without the aid of cannel coal, and to be producers also of pitch and anthracene of the very best qualities, with which no one could ever think of competing.

In conclusion, let us see how this would affect the illuminating power of the gas made by this process.

In the case of coal and cannel—

100 tons of ordinary coal give 10,000 feet of 17-candle gas.	
5 " cannel coal	12,000 " 28 "
Coal produce, 1000 @ 17 candles	17,000
Cannel " 60 @ 28 "	1,680

In all 1060 @ 17·6 candles.

Taking coal and gas-tar—

100 tons of coal give 10,000 feet of 17-candle gas.	
2·8 " tar oils	16,600 " 50 "
Coal produce, 1000 @ 17 candles	17,000
Tar oils " 48·5 @ 50 "	2,325

In all 1046·5 @ 18·1 candles.

In these calculations, I have taken 12 gallons of tar to be the produce from a ton of coal. If more tar is produced than this, the comparison will, of course, be more favourable. I have not gone to the length of calculating out the results according to the price of cannel, which must vary in every locality according to the cost of carriage; but I have endeavoured to show that the 7 tons of tar produced from 100 tons of coal is of value to the gas maker equal to nearly 10 tons of cannel coal. It therefore seems to me to be the height of absurdity to let the tar go away from the gas-works at some of the very low prices at present ruling; and, moreover, I have not reckoned in the values of the pitch and anthracene which would also be produced. One through retort will give about 500 cubic feet of gas per hour, besides a certain quantity of tar and ammoniacal liquor. This is equal to the decomposition of some 7 gallons of oil per hour.

In order to prevent misunderstanding, I may add that the process is patented, and I hope soon to see it at work.

DISCUSSION.

The CHAIRMAN said that the whole question of the enrichment of coal-gas by hydrocarbons needed much more scientific and systematic treatment than it had yet received. In some respects the methods in use were crude, and required always intelligent attention to produce satisfactory results. Mr. Davis's contribution to the solution of the question was interesting, and it appeared to him that the technical problem of producing gas of a high illuminating power and a more complete utilisation of the products of coal distillation had received an intelligent contribution to its solution by the author.

MR. FENNER said he understood Mr. Davis's idea to be that producers of coal-tar should utilise it for the re-production of gas, but it occurred to him that Mr. Davis had rather omitted to deal with anthracene and other hydrocarbons which were obtained. He would ask Mr. Davis whether the curious product chrysene had been utilised? He questioned, looking at the amount that gas-works obtained for their coal-tar, whether, if they were simply to convert it into gas, they would realise as much as now. If this idea were carried out, they might also not only become coal-tar distillers, but anthracene refiners, and perhaps in the future alizarin manufacturers.

Mr. MACKINNON said he had been engaged for the last three years in the very interesting problem of enriching coal-gas. He had been endeavouring to hit on the proper hydrocarbons to enrich coal-gas direct either by supplying it at the burner, or by passing the gas through a carburetter. He had tried a large number of hydrocarbons with various effects, and with regard to benzol he had observed the very curious fact which Mr. Davis had alluded to, that the illuminating power at the commencement was great, and then gradually diminished. If his surmise was correct, that benzol (commercial) was composed of three separate hydrocarbons, benzene, toluene, and xylene, he could believe that these hydrocarbons were absorbed by the gas in the order given. Some of the results he had obtained were as follows:—With a sample of 90 per cent. benzol, specific gravity 870·6, charge consumed 4469 grains, time occupied 52 hours 50 minutes, gas burnt 179 cubic feet, time for 1000 cubic feet 285 hours 10 minutes, residue left in carburetter, none. At the time the experiments were made the cost of benzol per gallon was 8s., it was now reduced to 1s. 11d. The total charge experimented upon was 5000 grains, and the weight 4353 grains; 1000 cubic feet of gas required 24,970 grains of the benzol, equal to ·403 of a gallon; the cost came to 3s. 4d. at 8s. a gallon. Total candles 3276; excess candles due to hydrocarbons 1026; excess of candles in cubic foot 456. The actual cost was 1s. 5d. A large number of experiments were made employing various hydrocarbons—for instance, a mixture of benzol, toluol, benzene and gasolene; also coal-tar distilled with naphtha and shale spirit. With the distillate of naphtha he obtained no less an increase than 6552 candles, whereas with benzol it was 3276. That convinced him that a distillate of naphtha might be found which would answer all purposes for enriching coal-gas, but in this case there remained a very large sediment of 696 grains unabsorbed by the gas, and, therefore, it was probable that the distillation should have been stopped at an earlier stage. The difficulty was to get each hydrocarbon of specific gravity, not mixtures as now. Benzol (commercial) was supposed to be composed of three different substances, but his impression was that it was composed of a much larger number, which had not yet been isolated, every one of which required a different degree of heat to volatilise, and the difficulty was to stop the process at the proper moment to get one uniform hydrocar-

bon, then uniform results could be obtained. Commencing with, say eighteen candles, employing a burner consuming three cubic feet, at the end of the consumption of the hydrocarbon you would have the same result ; but at the present, you commenced with eighteen or twenty candles and gradually went down to five or six. Mr. Mackinnon regretted that he could not take up more time in this matter.

Mr. Davis, in reply to Mr. Fenner, said he had mentioned that in the distillation of the coal-tar as it came from the ordinary hydraulic main one-third portion of the distillate was to run into tank called C. The anthracene was separated from that tank, and was hydraulically pressed for sale. The oils expressed from the anthracene contained some of the chrysene. Some would be sold with the anthracene, and the remainder go away with the pitch. With regard to the suggestion that these portions could not be carried out under the present Acts of Parliament, it need only be pointed out that a great many gas-works do now distil their own tars in both London and the provinces. The question was, however, whether tar would produce as much value when used instead of cannel coal as when sold in open market, and he had tried to show that seven tons of tar might be made equal to ten tons of cannel coal. It was, therefore, very easy without elaborate calculation to find out what tar should be sold at the various works. Mr. Mackinnon stated he had used ninety per cent. benzol for carburetting gas.* There was no doubt that ninety per cent. could be used if it were profitable, but from the solvent naphtha Dr. Letheby used there could be nothing but failure. Still, however, there is the gradual decrease in vaporisation to be got over even when using ninety per cent. benzol.

NOTES ON RUSSIAN TURPENTINE AND
ITS ATMOSPHERIC OXIDATION.

BY C. T. KINGZETT, F.I.C., F.C.S.,
Vice-President, Society of Public Analysts.

IN a paper communicated to this Society some three years ago by Dr. H. E. Armstrong,* attention was directed to the remarkable differences in the optical character of a number of samples of Russian turpentine; and from the rotatory powers then given in illustration of that fact, he infers that the proportions in which its two chief recognised constituents are present probably vary considerably, and that they are, perhaps, accompanied with other isomeric hydrocarbons.

I have found that not only do different samples of Russian turpentine present differences in optical character, but that they exhibit, also, equally striking differences in specific gravity and susceptibility to oxidation by air.[†]

For a long time I entertained the hope that a study of the physical properties of different samples, and the chemical history of their oxidation by air, would lead to the discovery of some simple relation between the results whereby the behaviour of any particular sample upon exposure to oxidation could be inferred beforehand. While, however, I have not been so fortunate in this respect as I had wished, the results seem to be of sufficient interest to warrant record.

Parcels of Russian turpentine bought direct from the importer, derived, it is believed, from a common

* Jour. Soc. Chem. Industry, 1882, p. 479.

† For a collective account of my investigations respecting the air oxidation of terpenes and allied substances, and the turpentine industry, see my book, "Nature's Hygiene," 2nd edition, chapters vi. and ix. (Baillière & Co.).

source, and obtained by the same distillation, are by no means uniform in quality; the contents of each barrel differ, as a rule, in one or more respects, from those of every other barrel. This variability in composition is, doubtless, attributable in the main to the method of distillation which is practised in Russia, but, in part, to the fact that the turpentine is not yielded by a single species of pine. Although the trees which are employed are chiefly the *Pinus sylvestris* and *Pinus ledbourii*, even they are not exclusively used; and as in the method of preparation the wood itself is subjected to distillation, it necessarily follows that at each stage of the process relatively different quantities of the several kinds will be undergoing both distillation and destructive distillation.

In the first place there is no evidence that the turpentines furnished by the *Pinus ledbourii* and other kinds of tree are identical with that obtained from the *Pinus sylvestris*. Further, there is reason to believe that the turpentine obtained from the different parts of a tree is not absolutely uniform in composition. For instance, Tilden* found that a sample of *Oleum foliorum Pini sylvestris* furnished upon fractionation two terpenes, one of which, smelling like ordinary American turpentine, boiled at 156° to 159° , but was more strongly dextrorotatory than australene (a column of 100mm. rotated the plane of polarisation $+18^{\circ} 48'$); whereas the other terpene

demonstrated the probable presence of furfurane (tetraphenol) and sylvane (C_4H_2OMe), a homologue of tetraphenol, in the low boiling portion of the wood oil obtained by the dry distillation of pine wood.†

Considering all these circumstances, it is not matter for surprise that Russian turpentine should, as found in commerce, present such want of uniformity in odour, colour, boiling point, specific gravity, optical behaviour and oxidisibility. Indeed, it would appear that the only method of obtaining an absolutely uniform turpentine oil (irrespective of kind) consists in the separative distillation (as distinct from destructive distillation) of one particular part of the trees belonging to a single species.

With reference to what follows, I should explain that it refers to manufacturing operations having for object the production of "Sanitas fluid" and "Sanitas oil," they being respectively the aqueous and oily products obtained by my process of air-oxidising turpentine in the presence of water at a temperature of about $60^{\circ} C$.

The results of the various experiments cannot be compared together, as the relative quantities of turpentine and water which were employed therein were not uniform, and the oxidation of the turpentine was not carried on for the same period in each experiment. In brief, the results attending the oxidation of any one sample of turpentine can only be compared with the results attending the oxidation of

boiled at 170° , but was levorotatory (per 100mm. = -4°), unlike sylvestrene (b. p. 171° to 171.5°), which is dextrorotatory (100mm. = $+17^{\circ}$). Tilden concluded, however, that it was sylvestrene, but this does not appear to be further proved. Later on, Atterberg† obtained from the oil extracted from the needles of *Pinus pumilio* a hydrocarbon which he also regards as identical with sylvestrene, but which exhibited rotatory power of -5.38 . The question arises, then, is this terpene, which resembles sylvestrene in its boiling point only (so far as yet proved), but which differs from it in its optical character, a distinct hydrocarbon?

Again, "pine cone oil," which is obtained by distilling with water the cones of *Abies pectinata*, differs in properties from "dwarf pine oil," which is similarly obtained from the young tops and cones of *Pinus pumilio*, while both of these oils are said to be dissimilar to "pine leaf oil," which is yielded by the leaves of *Pinus sylvestris*, or *Pinus abies*.

Lastly, the turpentine is undoubtedly accompanied with the products of destructive distillation of both rosin and the wood, including various hydrocarbons (cymene, benzene, toluene, xylene, paraffins, etc.), creosote, and tar and other acids. Atterberg has

other samples in the same series. In each series, however, the relative quantities of water and turpentine, the duration of the air-current, and the temperature at which the process was conducted, were as nearly identical as could be arranged upon the scale employed.

The rotatory powers (for columns of 200mm. of the turpentines used) in the first two series, were determined by Dr. H. E. Armstrong, as described in his paper to which reference has been made. In all the other series the reported rotatory values are merely the scale readings obtained upon examining layers of 200mm. in a "Portable Saccharimeter" (of Carl Zeiss of Jena, and supplied by Mr. Baker of London) by turning the rotating eye-piece until both semi-circles of the rock crystal plate acquired as nearly as possible the same reddish violet colour. I may, however, mention that two samples of American turpentine examined by this instrument gave the same scale reading of 23.5° .

The instrument consists of a glass tube, A, of exactly 200mm. in length, closed by parallel plates of glass, s s, at both ends, which is inserted into a brass tube, B. This brass tube carries a divided circle, C, divided by half-degrees, and upon this circle a shorter tube, D, rotates and contains a

† Ibid. Abstracts, 1882, p. 410.

‡ Journ. Chem. Soc. Abstracts, 1880, p. 663.

Nicol prism, *a* (the analyser). The rotation of *D* is measured on the divided circle by means of an index pointer, *d*. The other end of *B* bears, by means of an eccentric pivot, *F*, a short tube *E*, with another Nicol prism, *p* (the polariser), and a double plate of rock crystal, *g*.

The amount of oxygen absorbed by the turpentine in each observation was calculated by multiplying the increase in its specific gravity, by the number of gallons of the product.

The peroxide of hydrogen observed in the aqueous solution does not represent the whole amount obtainable, but only the quantity actually present therein at the time of examination.

The amount of peroxide of hydrogen obtained per lb. of oxygen fixed in the oil of turpentine has been calculated in each instance by dividing the grammes H_2O_2 by the lbs. of oxygen absorbed.

SERIES I.

Rotatory Power, 200mm. Turpentine used.	Lbs. of Oxygen absorbed by the Turpentine.	Grms. H_2O_2 obtained.	Grms. H_2O_2 obtained per lb. O absorbed by Turpentine.

	6.75	403	60

I should remark, in respect of this series, that as no accurate record has been kept of the quantity of aqueous product, I have been obliged to assume that exactly the same quantity was obtained in all instances. The last eight cases in the series serve to illustrate the difficulty experienced in maintaining as many oxidisers under absolutely identical conditions. Nevertheless, it may be noted that the average quantity of peroxide of hydrogen obtained in these eight cases, where the same bulked turpentine was employed, was 107grms. per lb. oxygen absorbed by the turpentine, and this figure agrees somewhat nearly with the oil of nearest rotatory power in the preceding cases, in each of which, turpentine from separate barrels, was oxidised.

SERIES II.

41	.8660	0.588	356	605

In this series the specific gravities of the oxidised oils, as also those of the turpentine employed, were determined by weight. It is seen from these results that Russian turpentine as met with in commerce ranges in specific gravity from '8620 to '8722, and that it contains from '496 to '237 per cent. of matter by weight in volume which is non-volatile at 100° C.

It is almost impossible to draw any conclusions regarding the production of peroxide of hydrogen in relation to the rotatory powers of the turpentine examined; but, if it be safe to conclude anything at all, it is that the oils of the higher rotatory values serve best, and that next in order come those of low rotatory value. If this conclusion be drawn, then we must look, not alone to sylvestrene (+34° per 200mm.: Atterberg, confirmed by Tilden) as the source from which the peroxide of hydrogen is obtained, but also to a hydrocarbon of comparatively high rotatory power not identical with the chief constituent of American turpentine (australene), for that substance is not readily oxidisable and is not a prolific source of peroxide of hydrogen.

I, however, hesitate to draw any fixed conclusion until a further series of observations have been made upon different samples of Russian turpentine to be submitted to oxidation in the same oxidiser under precisely identical conditions. In the meantime the results of my observations herein recorded have some interest of their own.

In conclusion, I may remark that I cannot confirm the statements which have been placed on record regarding the marked physiological effects, including violent headache, induced by Russian turpentine. Such effects have not been observed in the works of the Sanitas Company, Limited, where the air is always loaded with the vapour of Russian turpentine. On the other hand, the atmosphere is balmy and pleasant, and quite devoid of noxious properties.

DISCUSSION.

The CHAIRMAN said one of the questions which had yet to be solved was the chemical history of turpentine. The suggestion now made as to the possibility of different products coming from different parts of the tree was what might be expected from the exceedingly diversified manner in which the active principles of plants were distributed, and, where more than one active principle was found in the same plant, the very varied way in which they were severally distributed. For example, in a different branch of physiological chemistry, it was found in the distribution of the various cinchona bases in trees that one part of the tree would produce chiefly laevo-gyrate alkaloids, whilst the root of the same tree would produce chiefly dextro-gyrate alkaloids. There was nothing at all surprising, therefore, that one part of the same *pinus* should produce one form of oil of turpentine, whilst another part of the same tree would produce a totally different one. The question here opened up of the relation between the optical and the chemical properties of various turpentines to their oxidising power was a very interesting one, and probably these secondary actions of the turpentine might throw a considerable light on their constitution.

Mr. THOS. CHRISTY, agreeing with the chairman's remarks, thought that the products greatly depended on the nature of the sap, rising in the tree at the time. To obtain pistachios of fine flavour, trees had to be tapped to get rid of the turpentine, and prevent the flavour reaching the nuts. Possibly the character

of turpentine depended as much on the time of year as on the part of the tree from which it was extracted.

Mr. FENNER said as far as his experience with rosin spirit (to which substance Mr. Kingzett had verbally referred) went he had always found that either in the crude or rectified state it was a valuable article of commerce, quite irrespective of its being used as an adulterant. Brunswick Black, Black Japan, a black varnish, pine varnish, and many other useful articles were made with it. He remembered the time very well when he had sold highly rectified rosin spirit for as much as £80 a ton; at the present time if fairly rectified it was worth £15 to £16, as compared with turpentine at about £27. It was quite clear to his mind that no trading house would buy turpentine adulterated with rosin spirit, except to a very slight degree, because the odour of the two was so distinct that they could not well be mistaken. With reference to using it in paint, that could only be for rough work covering a very large surface, or making all descriptions of ship-bottom compositions. Russian turpentine was an article which had been known in commerce for many years, and was very useful in its way. Lately he had seen in the London market a beautiful article introduced from Poland, almost water-white, having a strong and distinct odour. In that case also he knew it could not be mixed or disguised in the shape of turpentine, and as far as his knowledge went of these various fluids they were highly useful, and had a fair commercial value.

Mr. KINGZETT, in reply, said he believed that less than ten years ago, Russian turpentine was comparatively a drug in the market, and was only employed by paint and varnish makers when American turpentine went up to a very high price. Since then his company had used large quantities, and had become, indeed, probably the largest consumers in the world of Russian turpentine, and consequently there had been an increasing interest in the article, so that now it competed to some extent with American turpentine in the English market for use in paint and varnish-making. So long as it was used fairly as a solvent which could be afterwards got rid of by volatilisation, he saw no objection to its use or even that of rosin spirit, for they served just as well as a high-priced turpentine. At the same time, he protested very strongly both as a chemist and as a business man against mixing rosin spirit with turpentine, and particularly to its being sold as turpentine. Whilst allowing that English-made rosin spirit had such a characteristic odour that even when present in a very small percentage admixed with turpentine it could be detected by the smell alone, the fact remained that rosin spirit as made on the Continent (in Germany) was quite a different product. It was very highly refined, and the highest qualities of this kind could not be bought at the present time under £19 to £20 per ton. It was possible to mix a large proportion of this substance with good Russian turpentine without detection, even by persons most familiar with the article, otherwise than by chemical means. The two samples of rosin spirit he had shown that evening were of this character, and when mixed with Russian turpentine the adulteration could not be detected except by analysis. Only recently he had a large parcel of so-called Russian turpentine offered him, which upon examination he found to be absolutely innocent of turpentine; it did not contain 1 per cent., being entirely German-made rosin spirit devoid of rotatory power. It was this reprehensible practice of adulteration which enabled merchants to offer Russian turpentine at any figure which would be likely to secure trade.

PROF. MILLS IN THE CHAIR.

THE SPECIFIC HEATS OF GASES AT HIGH TEMPERATURES.

BY DUGALD CLERK.

THE experimental determination of the specific heat of any gas at ordinary temperatures between 0° and 200° C. is a matter of very considerable difficulty. At elevated temperatures, 1000° C. and upwards, the difficulties so greatly increase that the method available for lower temperatures becomes quite impracticable. Until very recently no urgent commercial need pressed for exact knowledge on this subject. The steam and hot air engines hitherto brought into use dealt with their working fluids at comparatively low temperatures; accordingly chemists and physicists have not applied themselves to the exact determination of the necessary constants at the higher temperatures. Pure science, of which so much is now heard, seldom supplies motive sufficiently powerful to induce the necessary expenditure of means and labour always requisite for exact quantitative work. The requirements of industry, chemical and otherwise, have really given rise to most of the exact science of to-day, instead of, as is often represented, science originating industry. Under the stimulus afforded by the growth of the steam engine, physical constants for steam, for air and other gases and liquids, have been exactly determined; indeed, the whole science of thermodynamics seems to have originated in its study. Quantitative electricity, as an exact science, is largely indebted for its present position to the industrial requirements of the telegraph and the electric light.

In the same way quantitative chemistry has benefited from chemical industry.

The recent development, the gas engine, now urgently calls for accurate quantitative knowledge of many properties of gaseous explosion, both chemical and physical. At present but little is accurately known; the object of this paper is to point out what that little is.

Regnault experimented upon many gases by passing a given volume at a known temperature through a spiral tube surrounded with water contained in a vessel which formed the calorimeter, the temperature of entry and exit of the gas being observed together with the change in temperature of the calorimeter thermometer: the amount of heat added to or abstracted from the calorimeter is known, and therefore the capacity for heat of the gas. The results obtained are evidently the specific heats at constant pressure; the heat applied not only raises the temperature but it also causes expansion against a resistance, the atmospheric pressure. When the volume of the gas is kept constant by confining it in a closed vessel, less heat is required to raise it through a given temperature. Less heat by just the amount of work which would be done against atmosphere if expansion were permitted.

The specific heats are known as specific heat at constant pressure, and specific heat at constant volume, or sometimes as the apparent and true specific heats. Some physicists consider the specific heat of any substance at constant volume when in the truly gaseous state as the true specific heat of the substance in all states, and the difference between this and the values actually found for solids and liquids heated under ordinary conditions they consider to be due to the internal work done by the heat in expanding the solid or liquid against the cohesion proper to the substance.

The following are the specific heats of the gases concerned in a gaseous explosion for low temperatures as given by Regnault:—

SPECIFIC HEATS OF GASES (REGNAULT).

(Gases. Unit weights Water, 1. Unit volumes Air, 1.)

	Constant pressure.	Constant volume.	Constant volume.
Air	0.237	0.168	1.00
Oxygen	0.217	0.155	1.02
Nitrogen	0.214	0.173	1.00
Hydrogen	3.409	2.406	0.99
Carbonic Acid	0.216	0.171	1.55
Carbonic Oxide....	0.215	0.173	1.00
Water (Steam)	0.480	0.369	1.36

The specific heat of solid and liquid bodies is found generally to increase with increasing temperature, the increase being more rapid as the melting point is approached in a solid or the boiling point in a liquid. In gases very little change is observed, a slight change—an increase—occurring when it is easily liquefied—that is, when it is not greatly removed from its boiling point in the liquid state. The change is so slight that it has hitherto been assumed by many physicists that a perfect gas will not change appreciably its capacity for heat even at very elevated temperatures. The remarkable law of Dulong and Petit, that the specific heats of the elements, in similar states, when multiplied by their combining weights give a constant number, holds with but few exceptions. It is true with close approximation for the elementary nearly perfect gases, also for compounds which are nearly perfectly gaseous.

The molecular heat of an elementary gas is its specific heat at constant volume into twice the atomic weight; the molecular heat of a compound gas is its specific heat at constant volume multiplied by its molecular weight.

MOLECULAR HEATS OF GASES (CONSTANT VOLUME).

(Limits 0° to 200° C.)

	Specific heat at constant volume × molecular weight.	
Oxygen	0.155 × (16 × 2) =	4.96
Nitrogen	0.173 × (14 × 2) =	4.84
Hydrogen	2.106 × (1 × 2) =	4.21
Carbonic Acid	0.173 × (28) =	4.84
Carbonic Oxide	0.171 × 44 =	7.52
Water (Steam)	0.369 × 18 =	6.64

The members will kindly pardon these quotations of matters familiar to all of them; they are necessary for reference in what follows. In France, Messrs. Mallard and Le Chatelier,* and, later, Messrs. Berthelot† and Vieulle, consider that they have solved the problem of determining the specific heats of gases at temperatures approaching 4000° C.

Chatelier. If true they are, indeed extraordinary results.

But are they true? Do the experiments warrant the conclusions? In the author's opinion those scientists have been completely misled by the nature of their experiments; to him there does not seem the smallest reason for supposing any such change in the properties of gases.

The experiments consist entirely of measurements of the pressures produced by the explosion in a closed vessel of various mixtures of oxygen and combustible gases, H, CO, and many others, together with a diluting gas such as nitrogen, carbonic acid, or steam. The exact proportions of the gases were carefully measured, and therefore the total heat capable of being evolved on complete combustion was also known. Explosion was accomplished by

FIG. 1.

FIG. 2.

by a long and skilful set of experiments upon gaseous explosions. They are now agreed that contrary to general supposition, the specific heats of gases change very greatly with increasing temperature; at high temperatures, however, as at low, oxygen, nitrogen, hydrogen, and carbonic oxide still obey Dulong and Petit's law; their molecular heats are, within the limits of experimental error, still equal to one another.

Taking 4.8 as their mean molecular heats between 0° and 200° C., these chemists state that between 0° and 4500° C. the mean value becomes 9.8—that is, in passing from 0° to 4500° the capacity for heat so greatly increases that the average value is doubled. The molecular heat of chlorine at constant volume between 0° and 200° C. is 6.6; between 0° and 1800° C. it is 15.3. It is more than doubled.

Hydrogen 0° to 200° C. is 4.8 and 0° to 1800° C. it is 5.1.

Similarly steam, which is 6.6 between 130° and 230° C. is between 0° and 2000° C. 13.2, and between 0° and 4000° C. 19.9. Between 0° and 200° C. CO₂ is 7.52, and between 0° and 2000° C. it is about 18.0. All of those are Berthelot and Vieulle's figures. They are nearly in accord with those of Mallard and Le

the electric spark, and an indicator such as is used for testing steam engines made a tracing, which gave the maximum pressure produced by the explosion. From this maximum pressure may be calculated with considerable accuracy the corresponding temperature, assuming Charles' law of the expansion of gases by heat to hold for high temperatures as well as low. When this is done it is found that the temperature is not nearly so high as would have been anticipated, assuming complete evolution of heat and constant specific heat. This beautiful method of studying explosions was originated by Bunsen†, and he called attention to the fact of a great deficit of pressure, but explained it by assuming that at maximum pressure combustion is incomplete, dissociation setting a limit to temperature by the failure of chemical combination at the high temperature of the explosion. The French chemists differ from Bunsen, and consider that the influence of dissociation is trifling, the real explanation of the apparent suppression of heat being increase in the capacity for heat.

The author has made many experiments to determine the nature of gaseous explosions; the apparatus used consists of a strong cast-iron cylinder, of seven inches diameter and eight inches long internal measurement, accurately bored and the end covers

* Mallard and Le Chatelier, Bull. Soc. Chem. (2) 39; Chem. Soc. Journal (Abstract), 1883, p. 844.

† Berthelot and Vieulle, Annales de Chimie et de Physique, 1885, pp. 13–90.

‡ "On the Temperature of the Flames of Carbonic Oxide and Hydrogen," by R. Bunsen. Phil. Mag., 1867, vol. xxxiv. p. 489.

turned, so that the capacity was accurately known by measurement. Upon the upper cover is placed a Richards' indicator, in which the reciprocating drum is replaced by a revolving one; the rate of revolution is adjusted by a small fan, a weight through suitable gear giving the power. The cast-iron cylinder is filled with the explosive mixture to be tested, the drum is set in movement, the pencil of the indicator pressed gently against it, and the electric spark is passed between two points in the mixture. The revolving drum is enamelled, and the pencil is a black lead one. The pressure produced by the explosion acts upon the indicator piston, and a line is traced upon the drum which shows the rise and fall of pressure, the rising line traces the progress of the explosion, the falling line the progress of the loss of pressure by cooling. The curve obtained not only registers the highest pressure of the explosion, but it indicates the time taken to attain that pressure, and the time taken to lose it by cooling.

The curve supplies complete information of the whole course of the explosion, the maximum pressure, the time of explosion, and the time of cooling. Fig. 1 shows facsimiles of curves obtained from the explosion of hydrogen and air mixtures.

The following table gives the results calculated from these diagrams:—

EXPLOSION IN A CLOSED VESSEL.

(CLERK'S EXPERIMENTS.)

Mixtures of Hydrogen and Air. Temp. before Explosion 16° C., Pressure 14.7 lb. (Atmospheric).

Mixture		Max. press. above atm. in lbs. per sq. in.	Time of Explos.	Max. Temp. of Explos.	Calculated press. above atm. in lbs. per sq. in.
H.	Air.				
1 vol.	6 vols.	41	0.15 sec.	826 to 909° C.	88.3
1 vol.	4 vols.	68	0.026 sec.	1358 to 1539° C.	124.0
2 vols.	5 vols.	80	0.01 sec.	1615 to 1929° C.	176.0

The table clearly shows that temperature has been checked in some manner, the temperatures, and therefore the pressures, are but little more than half what they should be if all the heat is evolved by the moment of maximum temperature while the specific heat of the gases remains constant. The French chemists assume that all the heat is evolved, and the curves *B* and *C* do not contradict this assumption; but what is to be made of the curve *A*? The explosion is slower, the increasing line taking 0.15 sec. to attain maximum. When maximum is attained, the pressure does not begin to fall away at once, but remains stationary for nearly 0.07 sec. That is the mass of hot gas at a temperature of about 900° C., although in contact with cold cast-iron walls at a temperature of 16° C. appears to be losing no heat, the heat is necessarily flowing from it by the intense convection currents, therefore heat is being supplied at just the rate at which it is being withdrawn. The only source of heat here is combustion. In this instance combustion cannot be complete at the point of maximum pressure; any calculation of specific heat from the suppression of heat in this case would be plainly erroneous. When the pressure begins to fall in this case it falls very slowly, so slowly that it is impossible to say that combustion is complete even when fall commences, there is no reason to believe that it is. A further study of the three hydrogen curves will prove that even in *B* and *C* where fall commences immediately on the attainment of maximum pressure, there is every reason to believe that

combustion is still proceeding on the falling line. The falling curves *B* and *C* intersect at the point *D*, and the curve *C* falls below *B*. At the point of intersection *D*, in both experiments, the gases are at the same temperature, and if combustion was then completed, as required by the theory of Mallard, Le Chatelier, and Berthelot, then the gases from that point of similar temperature must cool at equal rate, the fact that *C* cools quicker than *B* shows that *B* must be receiving heat, or more heat than *C*, that is, combustion is still going on and adding heat. The curve *A* intersects *B* and *C* at about *E*, and it remains much above both; it is evident that combustion is keeping up temperature to a greater extent in *A* than in the other two. So much for hydrogen and air. Coal gas mixtures show the same phenomena, and something more. Fig. 2 shows facsimiles of curves obtained from Glasgow coal, gas, and air mixtures in the same manner, and in the same explosion vessel. The following table gives the results calculated from the diagrams:—

EXPLOSION IN A CLOSED VESSEL.

(CLERK'S EXPERIMENTS.)

(Mixtures of Glasgow Coal Gas and Air. Temp. before Explosion 18° C., pressure atmospheric.)

Mixture		Max. Press. above Atmos. in lbs. per sq. in.	Time of Explosion.	Max. Temp. of Explosion.
Gas.	Air.			
1 vol.	13 vols.	52	0.28 sec.	1017° C.
1 vol.	11 vols.	63	0.18 "	1265° C.
1 vol.	9 vols.	69	0.13 "	1384° C.
1 vol.	7 vols.	89	0.07 "	1780° C.
1 vol.	5 vols.	96	0.05 "	1918° C.

The curves *A*, *B*, *C*, *D*, *E*, Fig. 2, show in the most emphatic manner that combustion continues long after complete explosion, in *A*, *B*, and *C*, the maximum temperatures of 1047° C., 1265° C., and 1384° are sustained for a considerable time, necessarily by addition of heat from continued combustion, and curves *D* and *E* fall so gradually from maximum pressure that it cannot be for a moment assumed that combustion is complete at maximum pressure. The explosion part of the curve *E* shows a striking peculiarity; the explosion which causes the pressure to increase at a continually accelerating rate till 66 lb. pressure has been attained, suddenly seems to lose power of further increase, and at that pressure, about 1300° C., an actual fall occurs, lasting about $\frac{1}{100}$ part of a second. After that, an increase again occurs, till a temperature of nearly 2000° C. is attained, but the increase is never so rapid as at first. At first, the author was inclined to attribute this to a trick of the indicator, but the hydrogen curves taken with the same instrument exhibited no such peculiarity all of the coal gas ones do, as may be seen in *D* and *C* distinctly, and less distinctly in *B*. It is quite evident that a flame originated at one point in a mass of explosive mixture will spread with continual acceleration in a confined space, the compression of the un-inflamed portion by the inflamed portion causing a rapid rate of propagation of flame. No pause in increase of temperature can therefore be supposed to occur in a mixture while the flame continues to spread. The flame must be all through the mass before the pause at 1300° C. What then causes the increase after the pause? To the author it seems that the flame spreading through the mass burns the free hydrogen first, and then at the high temperature

1300° C., the hydrocarbons decompose and the remaining carbon and hydrogen combine with the oxygen more slowly at first causing increase of temperature, and then gradually overpowered by the cooling of the walls; on the downward curve heat is still being evolved but at too slow a rate to prevent fall. In these experiments the rate of rise of pressure is not great. Fig. 3 is the curve taken from a compressed mixture of gas and air in the same vessel, the time of explosion is 0.03 sec., and the maximum temperature remains constant for 0.1 second. Combustion must be continued at least during that $\frac{1}{10}$ sec., and there is no reason whatever for believing that it does not continue at a slower rate during fall.

These experiments, in the author's opinion, completely prove that whatever explanation is given, combustion, or burning, is not complete at maximum pressure; that is easily evident in many of the curves, and not one curve contradicts the induction. This being so, it is obviously impossible to say that the specific heat of these gases changes in the smallest degree by high temperature, so long as there is the faintest doubt of complete combustion at maximum

of flame varies from 2 feet in $\frac{1}{10}$ gas mixture to 14 feet per sec. in $\frac{1}{10}$ gas mixture, both Glasgow gas.

The author differs entirely, therefore, from Messrs. Mallard and Le Chatelier, and Messrs. Berthelot and Vielle, and considers that the experiments of those gentlemen do not prove any increase whatever in the specific heats of gases at high temperatures, and he asks the members of this Society to reject their results until it be proved by them that combustion is complete at maximum temperature of the explosions tested by them.

DISCUSSION.

Mr. ROWAN: There are very few persons who can discuss the subject of Mr. Clerk's paper in detail, as it is well known that the author is one of the pioneers in that field of research. I have followed his paper, as I did his previous one on "The Theory of the Gas Engine," in which this line of inquiry was foreshadowed, with very great interest, and think that his conclusions seem well founded. Nevertheless, I am not competent to pronounce a decided opinion on the subject. I should be glad if he could give a

FIG. 3.

pressure, Messrs. Mallard and Le Chatelier's experiments and Berthelot's values for the specific heats of gases at high temperatures are necessarily incorrect.

The error seems to have arisen in supposing combustion necessarily complete when the whole space is filled completely with flame, confusing complete inflaming of the mass with complete burning of it. In the case of solid fuel filling an ordinary grate, the whole mass may be vividly incandescent but yet not all consumed. In a coal or flour dust explosion every particle of the minute solid combustible may be incandescent, but some time will elapse, very minute certainly, but still measurable, before it will be completely consumed. The most rapid rise of pressure in such an explosion will occur necessarily when the flame is spreading, but the little particles may glow more fiercely after that and cause further rise, which rise will continue till the steady rate of cooling overpowers the rate of combustion. To get any certain value for the specific heat of a gas at a high temperature, a method of heating without combustion must be discovered.

These experiments give interesting information on many points, and show plainly the error of using the old method of calculating the *calorific intensity of a fuel*: the highest temperature obtained by burning hydrogen at constant volume does not exceed 1800° C., it should be 4100° C. The highest temperature of the explosion of Glasgow coal gas and air is 2000°, and the highest pressure, starting at atmospheric pressure, is 96lb. above it. The rate of propagation

reason for the fact that the actual maximum temperatures obtained in his experiments fall so far short, as he has stated, of the theoretical temperatures due to the explosions. If Mr. Clerk has made any analysis of the gases during different portions of the time represented in his diagrams, this would throw light on the question whether the combustion was incomplete, as he holds, at the point of maximum temperature and pressure. With regard to the flat portion of the indicator diagram, perhaps this might in part be due to the fact that the gases are under considerable pressure, and in expanding may give out some portion of the heat represented by the curve.

Mr. BELBY: The difficulty attending the measurement of instantaneous changes of pressure, which at first sight seems to militate against the accuracy of all such determinations, seems to have occupied the attention of MM. Vielle, Mallard, and Le Chatelier (*Compt. Rend.* 95, 1280 and 1352). Mr. Clerk, also, has evidently had this difficulty before him, and he will no doubt be able to show that his form of pressure indicator is fully competent for the work attempted. Notwithstanding a necessary reserve in accepting any of these measurements as actually indicating the *maximum pressures* of explosion, the evidence brought forward by Mr. Clerk leaves hardly a doubt that the failure of certain exploded mixtures of gases to reach the calculated pressure is to a great extent due to retarded combustion. In studying this retarded combustion, it would evidently be important to distinguish, and *separately* to determine the influence of (a) temperature, (b) pressure, (c) excess of

one or other of the active gases, and (*d*) ratio of surface to capacity of the exploding vessel. *a* and *b*. The influence of temperature and pressure should evidently be studied separately, as the dissociation temperature will most likely be raised by increased pressure. It seems a necessary preliminary to determine the dissociation temperature of gaseous water at low pressures, due account being taken of the nature and extent of the surface of the apparatus in which the dissociation is effected. *c*. Berthelot and Vielle have so far studied the influence of dilution of explosive mixtures with excess of either constituent or with a neutral diluent, but judging from the abstract of their paper in the *Chem. Soc. Journ.* (abstracts 1884, 804), the results are not conclusive. *d*. Recent researches on the influence of the metal of steam engine cylinders on the indicator diagram show such remarkably rapid transference of heat from steam to metal, and *vice versa*, even in comparatively large cylinders in which the ratio of surface to volume is small, that it seems not improbable that this ratio may influence the maximum temperature of gas explosions. Berthelot and Vielle evidently attach some importance to this ratio.

Professor MILLS: We are much indebted to Mr. Clerk for having brought before us the results of an extended range of experiments on this important subject. The propagation of chemical change has been but little investigated; and scarcely anything of an advanced character has been distinctly educed—viz., a single point in the theory of close fuses. Mr. Clerk's experiments and drawings show us very clearly that explosive combustion, even under very considerable pressure, is not a sudden but a gradual act, the maximum effect being attained much more rapidly than it is lost. This slow fading away of the effect is doubtless due to several co-operating causes, of which dissociation, due to the intense heat, is very possibly the chief. Pressure, on the other hand, would tend to accelerate the ignition; and ignition would presumably spread much more quickly in media of inferior viscosity. In endeavouring to explain complex phenomena of this kind, some assumptions have naturally to be made; but Mr. Clerk seems to have made out a strong case against the assumption that there is any increase in the specific heat of gases at a high temperature.

Mr. CLERK: It is difficult to give an explanation of the fact that the observed temperatures of actual explosions are so much lower than those to be expected on theoretical grounds, for the phenomenon is a complex one. In some cases—e.g., exceedingly explosive mixtures, dissociation must be the main cause, but this can hardly be so in other cases, as when very dilute mixtures are exploded. The experiments of the French chemists were made at intermediate temperatures, the only means they employed of altering the temperature of the explosion being to dilute their mixtures of gases. I cannot see that compression of the gases can effect the curve on the diagram, owing to the considerable velocity with which flame travels. I have made no analyses of the products of combustion at different periods of the explosion; it would be an exceedingly difficult matter to do so. The number and variety of the experiments made by Berthelot and the others are no proof of the truth of their results, for in all the assumption is made that the combustion at maximum pressure is complete, while my experiments go to show that this is not the case. These experimenters do not seem to have studied the crossing of curves as I have done. Further, in many experiments they used an inaccurate indicator—the Bourdon gauge with a pencil attached. I cannot believe that compression retards combustion. Sir Humphry Davy in his experiments

on the safety lamp, found the opposite to be the case. Thus, for example, he found that a mixture of hydrogen and oxygen in the proper maximum explosive proportions could not be exploded if the pressure was reduced to 1-18th of atmospheric pressure. Again, a mixture of 1 part of Manchester gas with 14 parts of air exploded with difficulty, while a mixture of 1 part of gas and 14½ parts of air does not explode at all, unless subjected to a slight increase of pressure. In a compressed gas the conversion currents have not the same freedom of motion as in an uncompressed gas, therefore in an explosion of the former there will be far less flow of heat through the sides of the vessel. The proportional surface for cooling is reduced, hence the flattening of the curve in explosions of previously compressed gases. It is impossible to increase the maximum pressure by diminishing ratio of cooling surface for similar mixtures of gases, except to a very slight extent. Berthelot and the others have not worked with compressed gases at all; my experiments on compressed mixtures are, I believe, the only ones yet published. It is not necessary to assume specific heats in order to calculate the temperature of the explosion: it is only necessary to assume that Charles' law holds good for high temperatures. The explosion vessel itself is used as a thermometer. Berthelot and Chatelier have no more right to say that the specific heats have altered than that Charles' law has failed. Experimental work is much required on this subject, as pointed out by Mr. Rowan, Mr. Beilby, and Prof. Mills. It is extraordinary that so little accurate knowledge is in existence on the subject of dissociation of water and carbonic acid.

Meeting held December 12.

ON THE COMPOSITION AND METHODS OF MANUFACTURING COMMERCIAL SULPHATE OF ALUMINA.

BY J. BEVERIDGE,

Of Ely Paper Mills, Cardiff.

THE varieties of sulphate of alumina found in the British market are salts of variable composition, and are met with under different names and in various degrees of purity. For many years past the more impure varieties have been known, and have had an extensive application in several of the great industries of this country, successfully accomplishing the object for which they were intended—i.e., displacing the more expensive salts, ammonia and potash alum. Quite recently, the manufacture of the pure salt has made a rapid advance, owing to the discovery of new methods of manufacture, and this advance is still likely to continue, principally because the product contains a high percentage of alumina, can be had perfectly free from iron, and in other respects commercially pure, and at such a price as to prove a much cheaper source of alumina than either of the alums.

The commercial salts produced by different makers differ somewhat in the percentage of Al_2O_3 they contain, and in this respect do not resemble the alums whose composition are well defined and practically constant. The want of uniformity in the different makes is said to have been advanced as an objection to the use of the salt by those consumers whose operations are so delicate that a slight alteration in the amount of alumina used will not produce the desired effect, and whose management is not so perfect as to calculate the exact amount required. Whether this be so or not I am unable to state, but it seems reasonable when we recollect the various delicate shades produced by the dyer and calico-printer. This difference in percentage of Al_2O_3 is merely noticeable when the products produced by different makers are compared, and does not generally exist when we consider each individual make. One of the best makers of sulphate of alumina in this country produces it containing no iron, and in other respects commercially pure, and having a practically constant composition of 16 per cent. Al_2O_3 .

The principal impurity, as is well known, in sulphate of alumina is iron, and in many industries the presence of this element renders the salt perfectly worthless. In the best qualities this impurity is absent, or nearly so, whilst in the lower qualities it ranges from a few hundredths to about three-fourths of a per cent. Consumers tend almost wholly to obtain the article as free from iron as possible.

As the ores of alumina do not exist in nature pure enough to be industrially converted directly into a sulphate which could compete with the alums, but are always more or less associated with iron, the main operation in this manufacture is the separation of

this body; and I propose placing before you a few details respecting the chemical principles upon which are founded the methods that have been proposed and adopted to accomplish this object, as well as to treat of the manufacture and composition of the cruder varieties.

The names under which the most important forms of sulphate of alumina are met with in this country are these:—

- (1) Aluminous cake.
- (2) Aluminous-ferric cake.
- (3) Sulphate of alumina, or concentrated alum.

Each of these varieties differs from the others in possessing some distinguishing feature—e.g., aluminous cake contains a large proportion of insoluble matter, which is absent in the other two, whilst aluminous-ferric cake, as the name implies, contains a large percentage of iron. Under the name sulphate of alumina, or concentrated alum, is included the salt having a low percentage of iron, or none at all, and in other respects commercially pure.

The raw material employed in this country as a source of alumina when manufacturing these compounds is either China or other clay, containing a small proportion of iron, or the mineral known as "bauxite." China clay is not now very largely used for the preparation of the pure salt, because it is much more difficultly soluble in sulphuric acid than either "alum clay" or "bauxite;" but it is the source of alumina in the manufacture of aluminous cake. The "alum clay" mined by the Eglinton Chemical Company is a valuable material, inasmuch as it contains little iron and, comparatively speaking, little silica on the alumina present; but as the alumina is partly combined with silica, it would appear to be somewhat more difficult to dissolve than "bauxite," whose alumina exists chiefly as hydrate. In practice the difference in solubility between these two minerals is not much, if any at all.

The analyses given on p. 17 show the composition of the various qualities of these raw materials.

I have calculated the amount of ferric oxide in each of these analyses on 15 parts of Al_2O_3 in order to show the relative amounts of iron to be got rid of when manufacturing the pure salt, as also the better to compare the aluminous materials themselves.

Comparing these analyses, it will be observed that the Cornish clay contains the least amount of iron on 15 parts Al_2O_3 , only the highest or "Gertrude" quality of bauxite approaching it in this respect. Usually, however, a less pure clay is employed containing from 0.4 to 0.75 per cent. ferrous oxide. I have found the proportion of silica to alumina in China clays to be fairly constant. In medium qualities the ferrous oxide seldom exceeds 0.45 per cent.

The other aluminous materials—viz., Irish hill "bauxite" and Eglinton "alum clay,"—both of which are found in extensive deposits in Ireland, and whose alumina exists largely as hydrate, are more easily soluble in sulphuric acid than China clay, and can be obtained nearly as free from iron. I say nearly, because there are China clays in the market containing less iron per unit of alumina than the purest variety of commercial "bauxite" or "alum clay." The insoluble matter from these Irish minerals, amounting to at least 25 per cent. of their original weight, is of a dark brown colour and has not the same commercial value as that from the Cornish clay, which is perfectly white when dried, and contains often more than 80 per cent. silica and may be used for a variety of purposes. Bearing these considerations in mind, and also comparing the relative costs of these aluminous materials, it would appear that China clay is as

cheap a source of alumina as either "bauxite" or "alum clay," notwithstanding it is more difficult to dissolve and requires to be well calcined and finely ground before being used.

These aluminous materials available for use in the manufacture of these salts contain too great a proportion of iron to enable the manufacturer to produce directly an article pure enough to satisfy many consumers; and, as the iron is as soluble in sulphuric acid as the alumina, it is necessary to remove this metal wholly or in part before the sulphate of alumina or concentrated alum of commerce can be obtained. Various attempts have been made to free the raw aluminous material of iron previous to acting upon it with sulphuric acid. Kynaston, Newlands, Condy and others have worked in this direction,

a sulphate of alumina containing not more than from 0.1 to 0.2 part metallic iron on 16 parts Al_2O_3 . As the separation of the iron in this and in analogous methods is at best only partial, and presents technical difficulties, such processes are of little value. All attempts based on the principle involved in the foregoing have therefore been abandoned in favour of the much more complete and practical methods recently invented to remove the iron from the sulphate of alumina liquors by mechanical or chemical means.

The aluminous materials above mentioned are not in a fit state, as they occur naturally, to be used directly in this manufacture. Irish Hill "bauxite" and Eglinton "alum clay" are both dried in order to expel the hygroscopic water, and are then finely ground. They may be obtained in this state or in lumps. China clay, on the other hand, requires to be

NOTE.—These analyses show the iron to exist in the ferric state, excepting the China clay. Both "alum clay" and "bauxite," as supplied by the respective companies, contain varying quantities of ferrous and ferric oxides.

principally with "bauxite." A process invented by the former of these gentlemen deserves notice, not only on account of its ingenuity, but also as the outcome of much exhaustive experimenting. Mr. Kynaston mixes the raw ground bauxite into a thick cream with water, and adds from 5 to 10 per cent. of its weight of oxalic acid together with an equal quantity of hydrochloric acid to prevent the formation of insoluble oxalates. The mixture is allowed to remain at rest with occasional stirring for a week or ten days. A large proportion of the iron goes into solution as oxalate, as also some of the alumina. The oxalates, etc., are removed from the bauxite by adding water and washing by decantation, and from the liquors the oxalic acid is recovered for use again by adding milk of lime in sufficient quantity to precipitate it as insoluble oxalate of lime, but not in such excess as to neutralise the hydrochloric acid present, which retains the iron in solution. The oxalate of lime after being washed is decomposed by boiling with an equivalent of sulphuric acid. Bauxite thus purified is said to produce

heated to a high temperature in order to expel all or nearly all the combined water. It is then ground, and if a high yield of soluble alumina be desired, it should be passed through a fine sieve and the sieved portion alone used.

SULPHATE OF ALUMINA FROM CHINA CLAYS.

Aluminous Cake.—One of the earliest and most successful attempts to introduce to the market a crude sulphate of alumina was made in 1855, by Mr. H. D. Pochin of Manchester. In that year Mr. Pochin obtained a patent for a preparation called by him "aluminous cake," made by heating together oil of vitriol and well-calcined finely-ground China clay. Since that time, and more especially since the patent right has expired, aluminous cake has been largely manufactured in many of the centres of industry in this country, and has found great favour amongst a certain class of consumers. It is one of the best and cheapest sources of sulphate of alumina obtainable by the paper maker, and in consequence

has been, and is now, largely consumed in this industry for sizing purposes.

The following analyses (three distinct makes of this article) show its general composition :—

	No. 1.	No. 2.	No. 3.
	Per Cent.	Per Cent.	Per Cent.
† Alumina.....	12.30	11.51	11.51
Ferric Oxide.....	.05	.16	.21
SO ₃	29.55	28.00	28.38

Water, MgO, Loss, etc. ..	31.10	37.28	37.81
	100.00	100.00	100.00

These analyses, when compared with others of crude sulphate of alumina, reveal a low percentage of Al₂O₃, with also a quantity of iron, which renders aluminous cake unsuited for many purposes. The amount of ferric oxide does not, however, interfere with the application of the salt in the paper industry, which practically consumes the whole of it produced in this country as a sizing material in the manufacture of cheap printing and other papers. It invariably contains free sulphuric acid, and often more than traces of arsenic. The insoluble matter, consisting of free silica and undecomposed clay, has a commercial value corresponding to its equivalent in pure China clay, because in the paper industry it serves as a loading material, and, therefore, it cannot be looked upon as an impurity.

As aluminous cake is made almost entirely for paper makers, it will be instructive to point out the essentials belonging to a good article, considered from a paper maker's point of view. It should be perfectly homogeneous, of a good colour, easily soluble, contain no gritty matter, no dirt, little or no free acid, and of course as much soluble alumina and as little iron as possible. The presence of lime as sulphate is not desirable. When it contains gritty matter, it acts injuriously on the press and other rolls of the machine; whilst if free acid be present in large quantity, and has not been properly neutralised by the rosin-soap added to fix the alumina, the acid liquor corrodes the knotted plates and fine wire cloth, upon which the paper is made, besides deteriorating the fibre, the felts of the machine, and acting injuriously on the drying cylinders. These are only a few of the evils caused by the presence of this and other impurities.

The care with which the manufacture of aluminous cake is conducted has given it a foremost place amongst sources of sulphate of alumina for makers of low qualities of papers. In point of cheapness and of purity it can hold its own with its substitute, aluminous-ferric cake; and as it has been in daily consumption in large quantities during the past thirty years, it will be very difficult to entirely displace.

Its manufacture is very simple, involving only one real chemical operation. China clay, as free from grit and iron as possible, is taken and calcined in a

reverberatory or muffle furnace, to expel the combined water, and after being withdrawn and cooled it is ground to a fine powder, and then sieved. The ferrous iron is, during the calcining operation, oxidised to the ferric state. The fine clay is then mixed with an equivalent quantity by weight of oil of vitriol of sp. gr. 1.615 (123° Tw.) in a lead-lined vessel, enough water being added to reduce the strength of the oil of vitriol to about 75° Tw. The mixture is heated slightly, when a violent chemical action soon takes place, 75 per cent. of the alumina and practically all the iron contained in the clay combining with the sulphuric acid to form soluble sulphates. Preferably the mass is kept hot till nearly all the acid has been saturated. When cool, it is ground into coarse fragments, and in this state sold. The proportion of acid and clay should in each operation be accurately measured, in order to produce a "cake" of regular composition. It is quite possible, by having the clay fine enough, and by continued heating with a slight excess of sulphuric acid, to obtain 85 per cent. of the alumina of the clay in the soluble form. This high figure is seldom obtained in practice. The "cake" contains all the impurities of the clay and sulphuric acid.

Commercially pure sulphate of alumina, and also the salt containing a small percentage of iron, may be manufactured from the liquors obtained by diluting with water the aluminous cake formed as described above, settling out the insoluble matter, and treating the clear liquors with some reagent for the partial or complete separation of the iron; but whether these processes are carried out industrially I am unable to state. The earliest attempt to accomplish this object was made about the year 1839, by Weismann, who in May of the following year obtained a patent entitled "Improvements in the Manufacture of Alum." His process consisted in adding ferro-cyanide of potassium to the clear sulphate of alumina liquors obtained from China clay, and containing iron; allowing the Prussian blue thus formed to settle, and finally boiling down the supernatant liquors. A few months later (in December, 1839), Robt. Hervey applied for a patent which was granted in 1840, for "Certain Improvements in the Mode of Preparing and Purifying Alum, etc., and the Application of such Improvements to the Purposes of Manufacture." Hervey's process is substantially the same as Weismann's, only his claim covers all combinations of ferro-cyanic acid. Seventeen years later Metcalf patented the same application.

The precipitation of the iron by ferro-cyanides is so marked a reaction, that at first sight it appears as the solution of the difficulty. The Prussian blue, however, is very difficult to completely settle, even after long standing, and unless its separation is complete the final product is coloured, which renders it quite unsaleable. Owing to this difficulty, it seems doubtful whether any of the foregoing processes have been carried out in practice. The separation of Prussian blue from aluminous liquors was not made a thorough practical success until about six years ago, when Mr. Kynaston, of St. Helens, succeeded in accomplishing it, simply and effectively.

SULPHATE OF ALUMINA FROM IRISH HILL "BAUXITE" AND EGLINTON "ALUM CLAY."

On the introduction of Irish hill bauxite about ten years ago to makers of salts of alumina, a great impetus was given to chemical research in this direction, chiefly because (apart from the growing importance of the pure salt) it contained a larger proportion of iron on 100pts. of alumina than what

* No. 1 is exceptional in purity, the low percentage of Fe₂O₃ being unusual.

† Equal to Al₂(SO₄)₃, No. 1, 41.07 per cent.; No. 2, 38.53 per cent.; No. 3, 38.53 per cent.

was usually found in China clays, and also because it contained such a large percentage of alumina, existing in great part as hydrate, that it presented itself as a cheaper and more convenient source. Not long after Mr. J. W. Kynaston, by much patient and laborious research, invented a process for the removal of the greater part of the iron as arsenite of peroxide, and, somewhat later, by applying Weismann's or the ferro-cyanide reaction, with certain improvements to the thus partially-purified liquors, he succeeded in producing a product which for purity was everything to be desired. Other workers came rapidly forward with inventions. Newlands, Semper, Spence, Kynaston again; and now the chemical activity has not ceased, judging from the list of applications for patents which appear in our Journal. In most cases detailed accounts of these processes have already been published, and it will be unnecessary to give a lengthy description of them. A short *resumé* of chemical principles involved in the most important of them will, I hope, prove interesting.

Starting with "bauxite" or "alum clay" and oil of vitriol, the first chemical operation is the formation of crude sulphate of alumina, and second, the purification of the crude aluminous liquor. Under the first head it will be convenient to treat of aluminoferric cake.

1st. The dissolving operation:—The apparatus required for this purpose is a large wooden or cast-iron tank fitted with a mechanical agitator, which is driven in any convenient way. Both vessel and agitator are protected by a covering of lead. A lead plug and seat are provided in the bottom of the vessel, so that the charge when finished may be run off. A plentiful supply of water must be near at hand, and also a small open steam pipe dips into the tub nearly to its bottom, so that the charge may be heated when necessary.

Into this vessel there are run about 67cft. of oil of vitriol of sp. gr. 1.615 (123° Tw.) cold, and after heating slightly by the injection of steam, there are added about twenty hundredweights of "bauxite" or of "alum clay." After a short time a violent chemical action sets in with the evolution of much heat, causing the mass to swell and rise in the vessel. When this has nearly ceased more bauxite or alum clay is added, in portions of about two or three hundredweights at a time. After each addition the chemical reaction is renewed, and in this way maintained until thirty hundredweights or so of the aluminous material has been added. A quantity of water is added to prevent the mass from "setting," and steam is injected until all or nearly all the acid has been saturated with alumina. Finally, it is diluted by the addition of cold water until it registers a density of about 40° Tw., and is run off into settlers, where the insoluble matter is allowed to deposit. The clear, cool sulphate of alumina liquor contains fully ninety per cent. of the alumina and iron originally contained in the bauxite or alum clay. It will show a density of about 37° Tw. when cold, and assuming first quality bauxite to have been used, will yield on analysis about 400 grammes of real $\text{Al}_2\text{S}(\text{SO}_4) + 18\text{H}_2\text{O}$, with which are associated from 2.0 to 2.5 grammes of metallic iron. The iron exists partly as ferrons and partly as ferric salt. There is always present a quantity of free acid amounting to seldom more than three grammes per litre, which represents about 1.75 per cent. of the total acid used; as also all the arsenic contained in the acid, and any lime, magnesia, and (if any) alkalis of the aluminous material.

The following is an actual analysis of one of these liquors made from first quality bauxite and ordinary arsenical oil of vitriol:

Sp. gr. = 1181 = 36.2° Twaddell.

Grammes per Litre.

$\text{Al}_2\text{S}(\text{SO}_4)$	= 193.12	= 57.92 grammes Al_2O_3
$\text{Fe}_2\text{S}(\text{SO}_4)$	= 1.80	= 1.791 Fe.
FeSO_4	= 3.52	
Free acid	= 1.57	
CaSO_4	= 2.60	
Water	= 977.13	

1180.13

Total solids by actual test, including free acid = 203.03 grammes.

Alumino-ferric Cake.—In 1875, the Messrs. Spence, of Manchester, obtained a patent for the manufacture of a crude sulphate of alumina, technically termed by them "alumino-ferric cake." This product has for a considerable time been produced by them in large quantities from the purer varieties of alum clay or bauxite, by dissolving these in oil of vitriol as described above. The crude aluminous liquor is roughly settled and boiled down to a suitable density, run off into trays to solidify, and the hard mass crushed into fragments, or sold in slabs. Thus manufactured, the "cake" has a brownish-grey colour, due to the presence of insoluble matter and contains all the impurities of the oil of vitriol, as also a very large proportion of the iron, etc., of the aluminous material. Free acid is always present. The insoluble matter exists in a very finely divided state and always in appreciable quantity.

Alumino-ferric cake was introduced as a cheap aluminous compound for the purposes of sewage defecation, and also as a substitute for aluminous cake in the paper industry, with which it differs in containing invariably a greater percentage of sulphate of alumina and practically no insoluble or "loading" material. It is largely used in this country and abroad for sizing purposes in the paper manufacture, and is in every way adapted for the production of every variety of low class papers.

The following is an analysis of alumino-ferric cake:—

Alumina.....	= 14.26	= 47.61 $\text{Al}_2\text{S}(\text{SO}_4)$
Ferric oxide	= .28	
Ferrous do.	= .32	= .64 Fe_2O_3
SO_3	= 35.36	
Free acid	= .45	
Insoluble	= .06	
Water loss, etc.,	= 19.10	

99.83

2nd. Purification of the crude S/alumina liquors. Much ingenuity and chemical skill has been brought to bear on this subject, and within the past six years as many processes have been invented, which appear to be perfectly successful commercially. They may conveniently be divided into two classes—namely, mechanical and chemical. By the former is meant those processes which seek to attain the end in view by mechanical means alone, whilst by chemical processes are meant those which by applying to the ferro-aluminous liquor a chemical reagent precipitate the iron.

1. *Mechanical Process.*—As far as I am aware, there is only one mechanical method in use on the large scale, invented by Mr. B. E. R. Newlands, in 1880, and is at present worked on an extensive scale by Mr. W. G. Strype, in the Dublin and Wicklow Chemical Company's works at Wicklow.

The crude aluminous liquor obtained directly by the action of oil of vitriol on bauxite or alum clay is perfectly settled, the free acid not being neutralised in any way, and is boiled down in lead-lined vessels to a density of 67° Tw. at its boiling temperature, at which strength it is run off into shallow lead-lined vessels to cool. About sixty per cent. (at most) of the total sulphate of alumina in the charge crystallises out in the form of flat scales, containing eighteen equivalents of water per equivalent of alumina.

lent of Al_2O_3 , the other forty per cent., together with all ferric and ferrous sulphate, remaining in solution as mother-liquor. The crystallised mass is broken up in any convenient way, and the resulting "magma" pumped or otherwise forced, with a pressure gradually rising till it equals about 200 lbs. per square inch, into a filter-press of special construction, the individual plates of which are covered with thick felt. In this way a hard cake of $\text{Al}_2\text{O}_3 + 18\text{H}_2\text{O}$ is obtained containing about 145 per cent. Al_2O_3 , and quantities of iron and water, in direct proportion to the amount of mother-liquor not removed.

A second and third crop of crystals are obtained from the first and second mother-liquor respectively, by concentrating and treating the magma from these in the same way as described for the first liquor. These two crops (second and third) contain a larger proportion of iron on the Al_2O_3 , than the first crop, but still very much less than what prevails in the original liquor, to which they may be added whilst this is being boiled down. By so doing, the liquor is enriched, and a purer first crop is obtained. The mother-liquor from the third crop is boiled down to a suitable density and solidified.

There are four distinct qualities of sulphate of alumina which can be made by this process, the three higher qualities corresponding to the three crops of crystals, and the lowest quality to the refuse liquor. By the kindness of Mr. Strype, of Wicklow, I am enabled to give the amount of iron on 1535 parts of Al_2O_3 or 100 parts $\text{Al}_2\text{O}_3 + 18\text{H}_2\text{O}$ in the different pressings, etc. :-

Original Bauxite Liquor.	1st Crop.	2nd Crop.	3rd Crop.	Residue.
Fe_2O_3 on 1535 parts Al_2O_3 ...	0.679 ..	0.065 ..	0.130 ..	0.259 ..
				2.312

It is interesting to observe the gradual increase in the amounts of iron in the various crops as the liquors are subjected to the concentrating and pressing operations. In the *first crop* of crystals the Fe_2O_3 is reduced to one-tenth the amount existing in the crude liquor. In the *second crop* the Fe_2O_3 , reckoned on the same basis, is twice the amount of that in the first crop, or, practically, one-tenth that contained in the mother-liquor from which it is obtained; and the amount of iron in the *third crop* is four times that of the first crop, twice that of the second, or one-tenth that of the mother-liquor from which it was obtained. The residue represents about 20 per cent. of the total alumina in the original liquor. From these figures it is evident that of 100 parts of sulphate of alumina in the original liquor, 80 parts are obtained in three crops, having an amount of ferric oxide representing about 15 per cent. of the original quantity. The other 85 per cent. of iron remains, of course, in the refuse liquor. Moreover it appears that the yield of sulphate of alumina in each pressing does not much exceed 50 per cent. of the total amount operated upon.

By using the finest, or Gertrude quality of bauxite, or any aluminous material equally free from iron, a sulphate of alumina can be made by this process containing not more than .04 per cent. Fe_2O_3 , but this amount is far too great to allow it to compete with the ordinary alums as a mordant in the dyeing and calico printing industries, and for this reason it may be called an imperfect process, as only 90 per cent., at the very most, of the purification can be accomplished.

2. *Chemical Processes.*—Of the chemical methods, the first which demands priority of place is that invented in 1879 by Mr. J. W. Kynaston, and to which I have already referred. It may be called

(a) *The Arsenic Process.*—It consists in precipitating the iron as arsenite of peroxide. The arsenious

acid used for this purpose is ground and mixed with a portion of the bauxite, along with which it is added to the batch in the dissolving vessel shortly after the vigorous chemical action between the aluminous material and sulphuric acid has begun. The arsenious acid goes into solution, and after the batch has been diluted with water to 40° Tw., and the ferrous iron has been oxidised by the addition of NaClO_3 or a hypochlorite, chalk, previously made into thick cream with water, is added in sufficient quantity to neutralise any free acid and to render the liquor basic. It is then run off into a large lead-lined vessel and allowed to settle. When perfectly cold, or after standing a few days, a sample of the clear yellow liquor is taken, and chalk added, when, if a deepening of the tint be observed, due to the formation of the arsenite, more chalk is added to the bulk of the liquor in the tank. Successive additions of chalk are added from time to time until all the arsenite that will separate has been thrown down. In twelve or fourteen days 90 to 95 per cent. of the iron will separate out, leaving a clear, supernatant liquor of a slightly yellow tint, containing a small quantity of arsenic. This latter is removed by running the liquor off into a stone tank and treating with calcium sulphide, the arsenic being of course precipitated as sulphide. When this has settled, the liquor produces by continuous evaporation a sulphate of alumina said to contain from 0.05 to 0.06 per cent. metallic iron.

Shortly after this invention was patented, Mr. Kynaston, seeking to produce a product which should be perfectly free from iron, applied Weismann's, or the ferro cyanide reaction to the liquor after settling out the bulk of the arsenite of peroxide of iron, but encountered the difficulties in completely settling out the Prussian blue previously mentioned. These were entirely overcome by adding a slight excess of ferrocyanide, and after settling a day or two introducing a few pounds of a zinc or a copper salt (preferably sulphates), not only to remove the excess of ferrocyanide, but also to agglutinate, as it were, the blue precipitate which, without such addition, persistently refuses to settle out. The liquor, after being further purified (from As and Cu or Zn) by treatment with CaS , was then boiled down to such a density as to yield on cooling a sulphate of alumina containing 16 per cent. Al_2O_3 , and pure enough to compete with the best ammonia and potash alums. The ferrocyanide used in this process is recovered as the calcium salt by boiling the well-washed Prussian blue with excess of milk of lime.

(b) *Binoxide Methods.*—To Messrs. Semper and Fablberg, I believe, the honour is due of having first introduced to makers of salts of alumina the use of a binoxide for the purpose of removing ferruginous contaminations from aluminous liquids. (See this Journal, vol. i. 275.) In 1882 these gentlemen patented the application of binoxide of lead for this purpose, and somewhat later Kynaston and Spence almost simultaneously that of binoxide of manganese. There is a distinct difference between the last two. Mr. Kynaston claims manganite of hydrogen, whilst Spence claims binoxide of manganese in whatever way produced. Laboratory experiments will easily prove that the hydrated binoxides are alone applicable.

It will be convenient to treat of these processes together, for when working them the chemical conditions to be fulfilled in each case, in order to yield the best results, are almost, if not, identical. They are these: The crude aluminous liquor must not contain free acid, but should be decidedly basic—basic at least to the extent of the sulphuric acid in combination with the ferric oxide. The iron should exist in the ferric state. Especially is this last condition

important in the case of the manganese process, for as Mr. Kynaston points out in his specification, if ferrous iron be present in the liquors along with manganite of hydrogen, it is oxidised at the expense of an equivalent quantity of MnO_2 , the resulting manganous oxide entering at once into solution as sulphate; and in order to free such liquors thus contaminated they must be subjected to another chemical operation. (This Journ. ii. 482.) Any lead which may go into solution in the lead process for the most part separates out during the concentration of the liquid as insoluble PbSO_4 .

Much of the success of these processes depends upon the care with which the hydrated binoxides are prepared.

Preparation of Hydrated Binoxide of Lead.—Dr. Fahlberg recommends that the hydrated binoxide of lead is best prepared by grinding together ordinary litharge PbO and common salt into a thick cream with water and allowing to remain for some time. A basic lead chloride is formed which is decomposed by the addition of a clear solution of bleaching powder, and when the resulting hydrated binoxide of lead is washed free from soluble chlorides it is ready for use. It should not be heated, as it loses its water of hydration, rendering it inactive.

Preparation of Manganite of Hydrogen.—Mr. Kynaston finds this already formed in the "manganese mud" of the late Mr. Walter Weldon's process, and recommends its preparation by treating the mud with a dilute acid (HCl , I presume) in order to remove the "bases," lime, and manganous oxide, which, together with hydrogen, are in combination with the MnO_2 . By so doing he renders the separation of these bodies easy. By simple washing they are removed, and when the manganite of hydrogen is perfectly free from MnO it is ready for use. There are other methods for the preparation of this reagent which will suggest themselves to the technical chemist.

Treatment of the Ferro-aluminous Liquids.—The operation of removing the iron from these liquors is performed by simply adding either of the binoxides, and agitating for some time until a sample withdrawn filtered and tested shows no iron reaction with ferrocyanides. When this is attained the binoxides are allowed to settle perfectly, and the clear liquor drawn off and further treated for the production of solid sulphate of alumina. In the manganese process should any Mn go into solution, Mr. Kynaston recommends its removal by precipitating it as MnO_2 , with free chlorine or a hypochlorite.

Recovery of the Binoxides for use again.—Both are recovered by first washing free from aluminous salt, and then treating them in the cold with a dilute acid—e.g., sulphuric acid. The iron which was in combination with the binoxides goes into solution as sulphate, and is removed from the revived binoxides by washing with water.

There are two other oxy-acids which have been proposed, and which are capable of performing the same work—namely, stannic and antimonic acids. The former of these is perhaps not admissible on a manufacturing scale, where large quantities of iron are to be removed principally on account of its great cost, and although it is quite capable of effecting the desired result, for this reason it will be unnecessary to treat of it further. Not so, however, with antimonic acid, the cost of which is one-third at most that of stannic acid. The manner in which these are used is identically the same as in the "manganese" and the "lead" processes.

From experiments which I have made recently with antimonic acid, and in which I have endeavoured to follow the lines that would suggest themselves to the manufacturer, not only in preparing the purifying

agent, but in its application, I find that it does the work with great rapidity, and as it is fairly stable it maintains its power during successive operations. As the atomic weight of antimony is considerably less than lead, I expect to find on further investigating this subject that antimonic acid will prove as cheap a material as peroxide of lead.

Thus far I have endeavoured to give a short account of the methods proposed within recent times for freeing aluminous liquors from iron, and it only remains to add a word or two in relation to these processes in general.

Of them all Mr. Kynaston's "manganese" process is obviously the cheapest, because the manganite of hydrogen is already formed in the source from whence he obtains it—viz., Weldon's "manganese mud," and also because manganese in the form of oxide is the cheapest available material. It is a process, however, which apparently requires much care and attention if the contamination of the liquors with manganese is to be avoided, and I venture to think in this respect differs from the other processes. This difference, however, is only one of degree, and not of kind, inasmuch as over all of them careful chemical supervision is necessary for successful work. In the "lead" process, should any lead go into solution it may be removed along with the arsenic derived from the oil of vitriol by precipitating both of them as sulphides with calcium sulphide, and the same is true of the antimony process should antimony go into solution. Products of equal purity can be made by the use of any of these oxy-acids.

When properly prepared, the relative amounts of hydrated binoxides required to remove one unit of iron bears such a relation to their relative molecular weights as would lead one to believe that the chemical compounds they form with ferric oxide correspond in constitution the one with the other. It is plain, therefore, that the amount of plumbite of hydrogen required in the "lead" process is greater than the amount of manganite of hydrogen required in the "manganese" process to remove equal quantities of iron. The exact constitution of the compounds which they severally form with the ferric oxide is not known. I have lately performed several experiments with all these oxy-acids in order to elucidate this point, with results which are not sufficiently uniform to warrant a definite statement.

None of these oxy-acids are stable enough to serve for an indefinite number of purifications, all of them becoming inactive after repeated use. This is owing principally (and only as far as I am aware) to dehydration, the iron hydrated compound being perfectly useless for the purpose in view. The item of cost of purification, therefore, is influenced not alone by the relative first cost of these oxy-acids, and by the amounts of mechanical loss always existing in manufacture operations, but also by their relative degrees of stability. The MnO_2 , after its purifying power has been spent, is still suitable for the production of chlorine, and probably no such useful value can be attached to either peroxide of lead or antimonic acid. The PbO_2 and Sb_2O_5 may of course be sold as such.

The arsenic and ferrocyanide method differs from these processes chiefly in the length of time required to completely remove the iron. Arsenite of peroxide of iron and Prussian blue are precipitates of a very light and flocculent nature, and they take a long time to completely settle. Mr. Kynaston himself states a month. This is not so in the oxide methods, the sulphate of alumina in which need not be more than a week in process. Hence there is a saving of plant in these oxide processes when compared with the arsenic and ferrocyanide method.

Of Newland's process, as I have previously stated, it may be said to be an imperfect one when compared with the chemical methods, as no sulphate of alumina can be made from it free from iron. The product, however, is very suitable for many purposes, and although the separation of the iron is not complete, and rather a large proportion of the original alumina is obtained in a very impure form, yet by it a product is made in a few days pure enough to satisfy the demands of many consumers as cheaply, I believe, as any of the other methods. Beyond this it is an interesting process, inasmuch as it is, I believe, the first mechanical one worked in this or in any country.

The following are analyses of sulphates of alumina:—

	NEWLAND'S			PURE SALTS.		
	Extra Quality.	Ordinary quality.	No. 1.	No. 2.	No. 3.	No. 4.
Al ₂ O ₃	11'84	11'70	11'95	11'85	16'00	16'20
Fe ₂ O ₃	'06	'12	'016	trace	nil.	trace
SO ₃	35'00	34'60	36'09	34'91	38'00	38'00
Free Acid.....	'32	'40	nil.	'29	nil.	nil.
Lime	'11	'11	'17	'11	'16	'11
Water	49'42	49'95	48'72	49'60	45'50	45'40
	99'75	99'88	99'97	99'82	99'66	99'74

The samples of Newland's process were kindly sent to me by Mr. Strype for analysis. No. 2 contained a notable quantity of manganese, which plainly reveals its origin. No. 3 is made by Mr. Kynaston's "arsenic and ferrocyanide" process, and is remarkably pure in every way. Not a trace of iron can be observed in it with the sulphocyanide of potassium test, which I think shows the great skill, ability and perseverance which he has shown in working out one of the most tedious processes, in my opinion, known to chemical technologists.

In conclusion, I have to thank Mr. George Blackwell, of the Irish Hill Bauxite Mining Co., for the samples of bauxite; and also Mr. W. J. A. Donald, of the Eglinton Chemical Company, for the samples of alum clay which they have kindly sent for exhibition.

DISCUSSION.

Mr. A. E. REED: I should like to ask Mr. Beveridge why he gives preference to aluminous cake before aluminous-ferric cake, for when the former is bought the value of it depends upon the amount of anhydrous sulphate of alumina it contains.

Mr. BEVERIDGE: In order to arrive at the real value of the sulphate of alumina found in aluminous cakes the value of the *loading material* or insoluble matter should be deducted from the cost of these, as this insoluble matter serves the same purpose as China clay in the paper industry.

The CHAIRMAN asked whether hydro-extractors had not been used in Newland's process for separating the mother-liquor from the crystallised S/alumina, and also referring to the chemical processes, if the oxides (MnO₂ and PbO₂) were dissolved by the aluminous liquor. Mr. Beveridge, in reply, stated that "hydros" had been tried, but he believed without success. The oxides were not dissolved unless a reducing agent was present.

Mr. R. W. ATKINSON said that although Mr. Beveridge had made no mention of the analytical

method employed in determining the alumina in his samples, it might be interesting to the members to describe a volumetric process recently proposed by Dr. Bayer in the *Zeitschrift für Analytische Chemie*. This process was based upon the fact that whilst sulphate of alumina was acid in its reaction to litmus, it was neutral to tropeoline. Hence, when an alkaline solution of alumina was coloured with litmus, the red colour appeared as soon as the alkali was neutralised, and sulphate of alumina commenced to be formed. When, however, tropeoline was used, the acid indication occurred only when the alumina first precipitated was completely redissolved. Thus the difference between the two amounts of standard acid used was a measure of the amount of alumina present. The speaker had found that litmus was not sufficiently sensitive, but that if it was replaced by phenol-phthalein the results were fairly accurate, and quite sufficiently so for practical purposes. The method undoubtedly had the advantage of simplicity and rapidity, and for technical purposes might well replace the tedious gravimetric method. Mr. R. T. Thomson had previously indicated a similar method, but had not thoroughly worked it out as an analytical process.

Mr. PRINGLE: For some time past I have been using a somewhat similar method to the one Mr. Atkinson refers to, for the estimation of *free acid* (sulphuric) and *iron* in the *pickling liquor* used for cleansing sheet-iron plates before tinning. The two indicators I use are litmus and phenol-phthalein. To a measured quantity of the pickling liquor I add caustic soda solution till the iron begins to precipitate, or until the litmus is coloured blue. The amount of soda taken is a measure of the free acid present. The iron may be estimated in the same solution by adding the caustic soda standard in slight excess, using phenol-phthalein as indicator. This method I have found to give quick and reliable results.

Journal and Patent Literature.

I.—GENERAL PLANT, APPARATUS, AND MACHINERY.

Improvements in Filters. E. M. Knight, Liverpool. Eng. Pat. 13,782, October 18, 1884.

Two perforated cylinders are placed concentrically in a containing vessel; the innermost cylinder is covered with asbestos cloth, and the space between the two packed with charcoal. The water is filtered from the container into the inner cylinder, which may further be furnished with an ice box, emerging therefrom by a pipe at the lower part of the apparatus. Sometimes the unfiltered water is admitted into the inner cylinder first, and the flow of filtered water is in the reverse direction.—C. C. H.

Improvements in Machinery or Apparatus for Refrigerating and Producing Ice, and in Liquid for the purpose. S. A. Varley and W. A. Gorman, London. Eng. Pat. 16,649, December 18, 1884.

This invention refers to the class of apparatus in which a carrying fluid, such as ammonia, which boils at a low temperature, is subjected to a partial vacuum for the purpose of lowering its temperature by evaporation, and then made to circulate through spaces which are surrounded by the liquid to be cooled. The production of the partial vacuum, as also the movements of the cooling liquor, are brought about by the expansion and contraction of two India-rubber tubes of special construction. These are placed concentrically in a closed

chamber, around a rotating shaft which carries rollers that pass over and close the tubes progressively whilst rotating, thus pushing the air and liquor before them. For fuller details, the printed specification and drawing must be consulted.—B.

Improvements in Filters. G. Haycraft, Lyme Regis.
Eng. Pat. 590, January 15, 1885.

THE patented improvement refers principally to the use

Description of Hot Blast Pyrometer (Krupp's Patent).
A. von. Bergen, Darlington. Journal Iron and Steel Inst., 1885.

THIS instrument will be understood from the illustration below. The hot blast enters at A, its pressure is regulated by cock H to a constant quantity, indicated by gauge E. Cold air is drawn in at B, the temperature of which is indicated on thermometer D. The gases mix in G, and, emerging from the apparatus, register their temperature on thermometer C. It is first necessary to obtain a co-efficient for the instrument by an absolute

KRUPP'S PATENT PYROMETER.

of a fibrous compressed filtering material, in the shape of flat discs of any form, held together in cases in such a manner as to produce tight joints around the edges of the discs with the view to preventing unfiltered water from finding its way into the interior or through the filtering material.—B.

determination of the temperature of the hot blast by means of Siemens's copper ball pyrometer, thus—

$$C = \frac{H - A}{F - A}$$

where C is the co-efficient, H temperature of hot blast, A that of cold, A and F that of the mixture. Having obtained this constant, the temperature of the blast may be found from the readings and the equation $H = C(F - A) + A - C. C. H.$

Improvements in and Apparatus for Evaporating and Concentrating Liquors and Depositing their Contents. G. S. Hazlehurst, Rhyl. Eng. Pat. 973, January 23, 1885.

THIS invention refers to apparatus for evaporating liquids and obtaining their crystals or deposits by means of movable endless surfaces of net, meshes, or strands, over which the liquor is allowed to spread, heat being applied underneath the chamber in which the apparatus is erected. The arrangement may consist of a number of parallel rollers, one series at the top and a corresponding series at the lower end of a vertical heating chamber, over which an endless net is laid and made to travel continuously. Above the upper rollers a series of tanks is placed, out of which the liquid drops and spreads upon the net, and is evaporated on its way by heat ascending from hot plates underneath. There are devices for detaching and collecting the resulting salts and deposits, for changing speed, for adjusting the net, etc., etc.—B.

Improvements in Capillary Filters. J. C. Newburn, London. From J. A. Tupper, Salt Lake City. Eng. Pat. 1489, February 3, 1885.

THE inventor makes use of capillary action for the purpose of filtration by arranging a number of tubes to project upwards from, and to pass downwards through the bottom of a vessel containing the liquid to be filtered. Wicks are placed into these tubes, their upper ends passing over the tops of the tubes and dipping into the liquid to be filtered, whilst their other ends project downwards through the tubes, thus acting as syphons. Several vessels constructed in this manner may be superposed one upon the other with the view to any desired number of repeated filtrations.—B.

Improvements in Filters. F. R. Lipscombe, London. Eng. Pat. 1510, February 3, 1885.

THE filter consists of two or more cylinders or other shaped vessels, made of a porous substance, or perforated and only covered with a porous substance. These cylinders are placed one within the other, the intervening spaces being filled in with charcoal or filtering material, either of which, as well as the top and bottom plates, may be removed separately for cleaning. The whole is inserted in a tank, the filtered water being withdrawn from the central or any other part of the filter.—B.

Refrigerating and Ice Machines. W. H. Wood, New York. Eng. Pat. 7824. June 27, 1885.

THIS specification describes various improvements in the mechanical details of vapour liquefaction pumps, and their adjuncts, used in refrigerating. The most important of these improvements consists in lubricating the interior of the cylinder by injecting into the current of vapour fed into the pump a spray-jet of the same vapour previously liquefied. The expansion of this into vapour in the interior of the cylinder greatly reduces, by absorption, the heat which would otherwise ensue from the compression of the vapour in the second part of the stroke. The remaining improvements are fully illustrated and described at considerable length.

—C. C. H.

II.—FUEL, GAS, AND LIGHT.

On the Behaviour of Mixtures of Carbon Dioxide and Hydrogen at High Temperatures. A. Naumann and C. Pistor. Ber. 18, 2724—2727.

IN order to ascertain whether hydrogen exerts a reducing action upon carbon dioxide, and at what tem-

perature this action commences, a mixture of dry carbon dioxide and hydrogen in the proportion of 1 to 3 was passed through a glass tube filled with small pieces of pumice-stone, at a temperature between that of the melting point of lead chloride (501°) and that of lithium chloride (602°). No formation of carbon monoxide took place. In a second experiment, conducted in the same manner at a temperature of 602° to 634°, the same negative result was obtained. Two more experiments were tried at a temperature between 861° and 954°, the gases passing through a porcelain tube of eight millimeters internal diameter. As in the previous cases, no change took place, thus proving that temperatures up to about 900° are insufficient to cause a reduction of carbon dioxide to monoxide by means of hydrogen. This result is supported by the fact that the heat of combustion of carbon monoxide is greater than that of hydrogen (to water in a gaseous form); further, by the great stability of carbon dioxide at high temperatures, no dissociation taking place even at 1700° when the gas is heated by itself, while it only commences to dissociate at 1300° when being passed through a porcelain tube filled with pumice-stone. The water which would be formed by the decomposition of the carbon dioxide by hydrogen would more readily be decomposed, the oxygen again combining with the carbon monoxide to regenerate carbonic acid. Contrary to the above observations, H. Traube (Ber. 18, 1891) found that by the influence of the electric spark upon a mixture of carbon dioxide and hydrogen a diminution of the volume of these gases takes place through the formation of carbon monoxide. Upon moist carbon monoxide, the electric spark remained without influence.—F. M.

Reaction of Carbonic Oxide and Water at High Temperatures. A. Naumann and C. Pistor. Ber. 18, 2894—2897.

A MIXTURE of carbonic oxide and steam (in about molecular proportion) was passed through a heated tube filled with pumice-stone. Below 600° no reaction took place; but at 600° it just commenced. At about 900° eight per cent. of CO₂ were formed, liberating the corresponding quantity of hydrogen from the water; and at about 950° ten and-a-half per cent. of CO₂ were produced.—A. G. G.

Improvements in Apparatus for Carburetting Gas for Lighting Purposes. W. G. Little, Conisboro. Eng. Pat. 17,108, September 30, 1885.

A TUBE, closed at one end and open at the other, contains a rod of solid hydrocarbon, preferably naphthalene. This tube is fastened in a vertical position, with its open end about an eighth of an inch above a horizontal iron plate. The whole is enclosed in a dome-shaped vessel, the bottom of which is the iron plate above mentioned. The gas to be carburetted passes by pipes suitably arranged over this iron plate to the burners situated just below. When these are lighted the plate becomes heated, and is covered by a film of melted naphthalene to the depth of one-eighth of an inch, kept at this depth by the arrangement above described. The gas passing over this film of melted naphthalene is impregnated with the vapour thereof. A suitable tap allows gas, if desired, to pass to the burners without passing through the carburetter.—A. R. D.

Improvements in obtaining Gas for illuminating and other purposes. J. F. Schnell and John Reed, Manchester. Eng. Pat. 690, October 16, 1885.

ATMOSPHERIC air is to be impregnated with the vapours of various compositions, and used for heating or illuminating gas respectively.—A. R. D.

Improvements in Condensing Apparatus for Treating or Purifying Coal Gas. George Love, Manchester. Eng. Pat. 2489, October 22, 1885.

THE gas on leaving the oven, generator, or producer, is led through a chamber where its course is rendered as

circumfous as possible by suitably-disposed screens or trays. In this chamber it is treated with water in jets, or very finely-divided spray.—A. R. D.

III.—DESTRUCTIVE DISTILLATION, TAR PRODUCTS, Etc.

Sylvic and Pimaric Acids. S. Haller. Ber. 18, 2165—2168.

WITH the exception of the percentage composition of sylvic and pimaric acids, the statements of various authorities in regard to the properties of these acids differ to such an extent that the author thought it of sufficient interest to investigate this subject. A supply of these acids in an almost pure condition being at his disposal, the final purification was effected by digesting the material in dilute caustic soda ley of about 3 per cent. strength, in which nearly two-thirds of the mass was soluble. The acids in the alkaline solution were reprecipitated by means of an acid, gelatinous flakes being obtained, which were thrown on a filter, washed carefully with water, and recrystallised. For the crystallisation of the pimaric acid, a large excess of the acid was mixed with hot 60 per cent. alcohol, and the hot solution filtered. On cooling, the acid was deposited in the form of a crystalline mass. The sylvic acid was crystallised from a minimum of alcohol, shining prismatic laminae being produced. The following numbers were obtained by analysis:—

Pimaric acid, C=78.47 and 78.62, H=9.41 and 9.62 per cent.;

Sylvic acid, C=78.85 and 78.65, H=9.78 and 9.62 per cent.

The softening points of these acids were 120° and 145°, and the melting points 149 and 161–162° respectively. The rotatory power of sylvic acid in an alcoholic solution was found to increase after each crystallisation until it became constant at $[\alpha]_D^{20} = -53$. Pimaric acid, when purified as above-described, is optically inactive.

The hydrocarbon obtained by Liebermann from these acids, by treatment with hydriodic acid and phosphorus, was prepared and examined by the author. An attempt was made to obtain numbers agreeing more closely with the formula $C_{10}H_{16}$ than those hitherto found. The results were not, however, sufficiently satisfactory, as can be seen by an inspection of the figures given in the original paper.

The hydrocarbons are optically inactive, and appear to be identical.—D. B.

Presence of Pseudocumene and Mesitylene in different kinds of Petroleum. C. Engler. Ber. 18, 2234—2238.

ABOUT six years ago the author proved the existence of pseudocumene in Pennsylvanian petroleum. Since that time other varieties, such as American, Russian, German, Galician and Italian petroleum have been examined, in all of which cumenes in the form of pseudocumene and mesitylene have been detected. American petroleum was found to contain about 0.2 per cent. of cumenes, whilst Russian petroleum showed only 0.1 per cent. The isolation was effected by digesting the fraction of the oil distilling between 170 and 190°, with a mixture of 2 parts of concentrated sulphuric acid and 1 part of nitric acid, the resulting mass being composed of trinitropseudocumene and trinitromesitylene. To separate these cumenes the mixture was treated with alcohol and heated on a water-bath for several hours. The solution contained the trinitropseudocumene, whilst the residue was composed of trinitromesitylene.—D. B.

Derivatives of Durene. J. U. Nef. Ber. 18, 2801—2807.

Durylic acid is obtained, free from cumidic acid, by heating durene with dilute HNO_3 (1 vol. HNO_3 1.4 to 3 vol. water) for 3–4 hours. The product is dissolved in NaOH, and precipitated with HCl. To free it from

nitro-compounds, it is heated with Zn and acetic acid, and finally distilled with steam.

Dinitrodurylic acid is prepared by dissolving the above acid in strong H_2SO_4 , cooling and then gradually adding KNO_3 . The pure compound is obtained by decomposing the lime salt.

Dinitropyromellitic acid is obtained by the oxidation of dinitrodurylic acid in an alkaline solution with $KMnO_4$. The mass is filtered, acidified and extracted with ether. On distilling off the ether, 2 compounds remain, a tri- and tetra-basic acid. They are separated by adding methylated spirit to the concentrated solution of the lime salts, when the salt of the tetrabasic pyromellitic acid is completely precipitated. The silver salt gave, on analysis, the formula $C_{10}(NO_2)_2(CO_2Ag)_4$. It could not be reduced to the corresponding amido-compound. The ethyl ether, however, on reduction with Zn and acetic acid, yields an azo-body of the formula $C_6N_2(CO_2C_2H_5)_4$, and possessing a deep cinnabar-red colour.

Durenequinone is obtained from diamidodurene by oxidation with sodium nitrite, or Fe_2Cl_6 in an acid solution.—J. B. C.

Derivatives of Durene. O. Jacobson and E. Schnapauff. Ber. 18, 2841—2844.

DURENE, brought in 2½ times the weight of chlorosulphonic acid, forms durene-sulphonic chloride $C_{10}H_{13}SO_2Cl$, and in addition durylsulphone $(C_{10}H_{13})_2SO_2$, and durene-sulphonic acid $C_{10}H_{13}SO_3H$. If the resulting semi-solid mass be treated slowly with ice-cold water, the sulphonic acid may be separated by filtration from the other two compounds. The filtrate is then saturated with NaOH, and the sodium salt crystallises out. Durenesulphonic chloride may be separated from sulphoduride by crystallisation from alcohol and ether. Durylsulphone remains in the mother liquor, and it may be obtained in the pure state by heating with alcoholic NaOH, precipitating with water and crystallising from dilute alcohol. If the sulphonic acid only be required, the residue left, after separating the first portion of the sulphonic acid, is dissolved in alcohol, and heated with an excess of dilute NaOH on the water-bath. Water is added, and the whole mass cooled, when the sodium sulphate separates out, and the durylsulphone may be extracted with ether. These three compounds are crystalline bodies possessing the general properties of their class.

Dureneol $C_{10}H_{13}OH$ is obtained in the usual way by fusing the sodium salt of durenesulphonic acid with KOH. It is a solid body, m.p. 117°. On protracted fusion, hydroxydurylic acid is formed of the formula— $C_6H(CH_3)_3(OH).CO_2H$.—J. B. C.

IV.—COLOURING MATTERS AND DYES.

Isomeric dihydroxydimethylanthraquinones. S. v. Kostanecki and S. Nientowski. Ber. 18, 2138—2141.

IN a previous communication (Ber. 18, 250) it was shown that concentrated sulphuric acid reacts with symmetrical hydroxytoluic acid in the same way as with meta-hydroxybenzoic acid. The product was separated into two portions by the action of baryta water, and from the insoluble residue a dihydroxydimethylanthraquinone was isolated, which the authors described as dimethylanthrarufin. By the action of hot acetic anhydride and sodium acetate *acetyldihydroxydimethylanthrarufin* $C_{16}H_{16}O_2Ac_2$ was obtained. This compound forms yellow plates melting at 236 to 237°. The portion soluble in baryta water was treated with hydrochloric acid, the resulting precipitate washed with water, and extracted with boiling alcohol. The sparingly soluble dimethylanthraflavic acid remains in the residue, whilst the alcoholic solution contains dimethylmetabenzodihydroxyanthraquinone, and a small amount of dimethylanthraflavic acid. *Dimethylanthraflavic acid* $C_{16}H_{16}O_6Me_2$ sublimes in yellow needles, melting at 360°. It is insoluble in benzene, sparingly soluble in alcohol, and glacial acetic acid, and resembles anthraflavic acid in many of its properties. The spectrum is almost coincident

with that of the latter. The alkaline solutions are yellow. Mordants are not dyed by it. The acetyl compound crystallises from alcohol in pale yellow needles, melting at 223°. The isolation of the dimethylbenzodihydroxyanthraquinone was effected by adding lead acetate to the alcoholic solution, filtering and concentrating the filtrate, when yellow needles were obtained, which were purified by extraction with benzene and recrystallisation from alcohol.

Dimethylbenzodihydroxyanthraquinone— $C_{14}H_{10}O_4(CH_3)_2$ —crystallises and sublimes in needles, melting at 213°. It yields a brown solution with concentrated sulphuric acid, the spectrum of which resembles that of metabenzodihydroxyanthraquinone. Its alkaline solutions are golden yellow. The acetyl compound forms needles, melting at 188°. Although the product of the action of concentrated sulphuric acid and symmetrical hydroxytoluic acid is identical with that of metahydroxybenzoic acid, the relative yields of the isomerides differ. Whilst crude anthraflavone produces mainly anthraflavic acid, the chief product from dimethylantraflavone is dimethylanthrarinin.—D. B.

On the Action of Diazo-compounds on β -Naphthylamine, and on α - β -Naphthylenediamine. (Second Communication.) T. A. Lawson. Ber. 18, 2422–2427.

IN a previous paper (this Journal, iv, 395), the author has described some products of the above reaction, which behave partly as diazoamido and partly as amidoazo-compounds, or derivatives of naphthalene with two ammonia residues as side chains. The compound obtained by the action of amyl nitrite on β -naphthylamine belongs to this class, is identical with that obtained by combining diazo- β -naphthylamine with β -naphthylamine, and behaves in the same way as benzenediazo- β -naphthylamine. From this it appears that β -naphthylamine always gives diazoamido derivatives differing in certain reactions from those diazoamido bodies hitherto known.

Reducing agents decompose β -naphthalenediazo- β -naphthylamine into β -naphthylamine and α - β -naphthylenediamine, m.p. 96°. The fact that no hydrazine is produced, and the formation of a naphthylenediamine, points to the preliminary change into amidoazo-compounds, but all efforts to form and isolate these bodies have failed. With aniline and aniline-hydrochloride, the reaction commenced at 100°; traces only of a substance melting at 136° were however formed. β -naphthalenediazo- β -naphthylamine $C_{16}H_7N=N-NH(C_{10}H_7)$ crystallises from alcohol in needles m.p. 149°. Boiled with dilute sulphuric acid this body is decomposed, nitrogen being evolved. The acetyl and benzoyl compounds are sparingly soluble in alcohol and petroleum spirit, easily so in benzene. Treated in acetic acid solution with bromine, these diazo-compounds are decomposed, bibrom- β -naphthylamine is precipitated, bromophenols remain in solution and nitrogen is given off. *Dibrom-naphthylamine* $C_{10}H_7Br_2NH_2$ is a weak base, forming colourless needles easily soluble in alcohol and benzene, m.p. 121°. The acetyl-compound melts at 208°.

The naphthylenediamine hydrochloride obtained on reduction from these bodies reacts with benzaldehyde at 100°, with formation of a base melting at 103° and decomposing at 120°. With phenanthrenequinone, phenanthrene-naphthaquinoxaline is obtained, $C_{12}H_8 : (CN)_2 : C_{12}H_8$, which crystallises from benzene in small yellow crystals, m.p. 273°. They are insoluble in alcohol, and are reddened with HCl. Warmed on the water bath with benzil in alcoholic solution, diphenyl-naphthaquinoxaline, $C_{10}H_6 : (CN.C_6H_5)_2$, is produced, forming light brown plates easily soluble in alcohol and ether. Lellmann's reaction was unsuccessful, but the above reactions prove sufficiently this naphthylenediamine to be α - β or β - β -ortho-derivative. Other experiments show it belongs to the same class as β -naphthoquinone, therefore it is α - β -o-naphthylenediamine, and the same naphthylenediamine is easily obtained from α -nitro- β -naphthylamine.—T. L. B.

Benzylhydroxanthranol. L. Levi. Ber. 18, 2152.

THIS compound is best prepared by adding 5 parts of benzylbromide to a boiling mixture of 5 parts of anthraquinone, 5 parts of zinc-dust and 7.5 parts of potash dissolved in 100 parts of water. The resulting benzylhydroxanthranol $C_{21}H_{16}O_2$ is readily soluble in alcohol, benzene, glacial acetic acid and melts at 146°. It crystallises from benzene in fine white plates. Cold concentrated sulphuric acid converts it into dehydrobenzylhydroxanthranol $C_{21}H_{14}O$. The latter forms long yellow needles melting at 127°.—D. B.

On Mixed Azo-Compounds (II.). E. Bamberger and A. Cahman. Ber. 18, 2563. (See also, 17, 2415.)

THE sodium compound of ethyl-aceto-acetate acts upon the nitrated diazo-compounds forming mixed azo-compounds (Bamberger, Ber. 17, 2415), sodium benzoyl-acetic ether was found to act in a perfectly analogous manner. *Phenylazoacetophenone* $C_6H_5-N_2-CH_2-CO-C_6H_5$ and *phenylazobenzoylelactic acid* $C_6H_5-N_2-CH(COOH)-CO-C_6H_5$. By slowly adding to a well-cooled neutral solution of diazobenzene chloride a solution of benzoyl-acetic ether in an equivalent quantity of caustic soda, a reddish-brown resin separates out, consisting of a mixture of phenylazoacetophenone and phenylazobenzoylelactic ether. By heating this with an alcoholic solution of potash and adding water to the solution obtained the ketone is separated in yellow flakes, while the acid formed by the saponification of the ether remains in solution and is obtained from it by the addition of a mineral acid. *Phenylazoacetophenone* forms golden yellow needles, melting at 128.5°. It is readily soluble in hot alcohol and glacial acetic acid. *Phenylazobenzoylelactic acid* crystallises from acetic acid and dilute alcohol in long lemon-yellow needles, melting at 141°, and is readily soluble in hot ether, alcohol, and acetic acid. By boiling this acid with a dilute solution of caustic soda, phenylazoacetophenone is formed, which separates out in the shape of small crystals. This reaction is analogous to that observed by v. Richter and Münzer (Ber. 17, 1926) and Bamberger (Ber. 17, 2415) in case of the azo-derivatives of aceto-acetic ether.

Ortho-nitrophenylazoacetophenone— $NO_2.C_6H_4.N_2.CH_2.CO.C_6H_5$ [$NO_2 : N_2 = 1 : 2$]-and *ortho-nitrophenylazobenzoylelactic ether*— $NO_2.C_6H_4.N_2.CH(COOH).CO.C_6H_5$ [$NO_2 : N_2 = 1 : 2$]-are prepared according to the method given by the author in his first paper (Ber. 17, 2415). The former crystallises in shining, golden yellow needles, pretty soluble in the ordinary solvents, and melting at 140 to 141°. The latter forms sulphur-yellow, silky needles, readily soluble in hot glacial acetic acid, less in cold acetic acid, alcohol, and ether. It melts at 177°. By heating it to this temperature for some time it is converted into ortho-nitrophenylazoacetophenone.

Meta-nitrotolyl-para-azobenzoylelactic acid— $C_6H_5(CH_3)(NO_2).N_2.CH(COOH).CO.C_6H_5$ [$CH_3 : NO_2 : N_2 = 1 : 3 : 4$]-prepared from meta-nitro-paratoluidine (m.p. 114°) and sodium benzoyl-acetic ether—golden-yellow needles with a silky lustre, melting at 194°.

Meta-nitrotolyl-para-azoacetophenone— $C_6H_5(CH_3)(NO_2).N_2.CH(COOH).CO.C_6H_5$ [$CH_3 : NO_2 : N_2 = 1 : 3 : 4$]-forms lemon-yellow needles, melting at 168° (?). By adding hydroxylamine, and an equivalent quantity of caustic soda to an alcoholic solution of this compound, a ketoxime, crystallising in reddish-yellow needles, and possessing the formula $C_6H_5(CH_3)(NO_2).N_2.CH_2.C(OH).C_6H_5$ [$CH_3 : NO_2 : N_2 = 1 : 3 : 4$] is produced.

—F. M.

Derivatives of Pseudocumenol. K. Auwers. Ber. 18, 2655–2660.

THE methyl-ether of pseudocumenol— $C_6H_5(CH_3)_2.OCH_3$ [$1 : 3 : 4 : 6$]-is a colourless fluid, which boils at 209°–211°.

Monobromopseudocumenol— $C_6H_5(CH_3)_2(Br)OH$ —is formed by bromination of pseudocumenol dissolved in acetic acid. It crystallises in yellow needles, melting at 35°; insoluble in water.

Dibromopseudocumenol— $C_6H_3(CH_3)_3(Br)_2.OH$ [1:3:4:2:5:6]—obtained by further bromination of the preceding, forms long colourless prisms or needles, which melt at 149° , are insoluble in water, but tolerably soluble in alcohol, benzene, and acetic acid, and very easily in ether and chloroform. Its methyl-ether— $C_6H_3(CH_3)_3(Br)_2.OCH_3$ —crystallises from acetic acid in thick white needles, insoluble in water, and melts at 96° .

m-Nitropseudocumenol— $C_6H_3(CH_3)_3(NO_2).OH$ [1:3:4:2:6]—is obtained by evaporating an alcoholic solution of nitropseudocumenolnitric ether— $C_6H_3(CH_3)_3(NO_2).ON.O_2$. It melts at 48° , and is tolerably soluble in hot water, very easily in other solvents. It dissolves in alkalis with a deep-red colour. By dilute HNO_3 it is reconverted into the nitric ether. Its methyl ether— $C_6H_3(CH_3)_3(NO_2).OCH_3$ —forms large transparent prisms, or rhombic tables, which melt at $41-42^\circ$, and is very soluble in all ordinary solvents except water.

Dimitropseudocumenol— $C_6H_3(CH_3)_3(NO_2)_2.OH$ —is formed by the action of NH_3 in ethereal or alcoholic solution on *m*-nitropseudocumenolnitric ether, or better by passing a stream of dry NH_3 gas over the finely-powdered compound. It melts at 112° .

Dipseudocumenol— $C_6H_3(CH_3)_3.OH$ —is best prepared by oxidation of pseudocumenol with a solution of $K_2Cr_2O_7$ in acetic acid, the yield being 50–60 per cent. It is also formed by oxidation of pseudocumenol with Fe_2Cl_6 or dilute HNO_3 . It crystallises in long needles or small hexagonal crystals, and melts at 173° . Its dimethyl ether— $C_{12}H_{15}(CH_3)_6(OCH_3)_2$ —melts at 126° , and is insoluble in alkalis. By bromination in acetic acid solution the dicumyl yields—

Dibromodipseudocumenol— $C_{12}H_{15}(CH_3)_6Br_2(OH)_2$. This forms small glistening crystals, which melt at $186-187^\circ$, are easily soluble in alcohol, acetic acid, and ether, sparingly in alkalis, and insoluble in water.—A. G. G.

On the Amido-azo-derivatives of the Three Xylenes. E. Nölting and S. Forel. Ber. 18, 2681–2686.

Up to now only one amido-azo-xylene was known, which had been obtained by Nietzki from commercial xylene (Ber. 13, 472). The authors prepared the amido-azo-derivatives from the pure xylenes in order to compare them with Nietzki's compound. The latter was found to be a mixed compound, containing meta-xylene in one and para-xylene in the other nucleus (with the NH_2 group).

Amido-azometaxylene— $C_6H_3(CH_3)_2N = NC_6H_4(CH_3)(CH_3)NH_2$. [$CH_3 : CH_3 : N$ and $N : CH_3 : CH_3 : NH_2 = 4:2:1$ and $6:4:2:1$]. This body is prepared by mixing in a beaker placed in a freezing mixture 121grms. metaxylidine with 157grms. metaxylidine hydrochloride, and adding gradually a 20 to 25 per cent. solution of 69grms. sodium nitrite. The diazo-amido compound thus formed is extracted with ether, and after evaporation of the latter, mixed with 120grms. metaxylidine and 10 to 15grms. metaxylidine hydrochloride. The mixture is heated in a water-bath to 50° until a sample heated with acid does not give off any more nitrogen. The hydrochloride of the amido-azo compound which remains behind on treating the mixture with moderately dilute boiling hydrochloric acid is, after washing with water, alcohol, and ether, decomposed by means of ammonia. The base is purified by recrystallisation from alcohol or benzene. The same process is adopted for the preparation of the other amido-azo-xylenes. Amido-azometaxylene crystallises in fine orange-yellow scales, melting at 78° . The hydrochloride is a bright-yellow powder, dissolving in alcohol and more readily in phenol, with a beautiful green colour. By the reduction with stannous chloride and hydrochloric acid a diamine is formed (besides metaxylidine), melting at 77° to 78° , and giving all the reactions of the ortho-diamines.

Amido-azometaxylene— $C_6H_3(CH_3)_2(CH_3)N = NC_6H_4(CH_3)(CH_3)NH_2$. [$CH_3 : CH_3 : N$ and $N : CH_3 : CH_3 : NH_2 = 6:2:1$ and $4:6:2:1$]. Yellow scales, readily soluble in strong alcohol and benzene; melting-point, 77.5° . The hydrochloride dissolves in alcohol and phenol, with a red colour. The diamine forms a quinone, which

fact, supported by the impossibility of obtaining (under the ordinary conditions) amido-azo compounds with the $N=N$ group in meta-position to the amide, and the red colour of the hydrochloride, seems to give proof for the correctness of the above formula.

Amido-azometaxylene— $C_6H_3(CH_3)_2N = NC_6H_4(CH_3)(CH_3)NH_2$. [N and $N : CH_3 : CH_3 : NH_2 = 1$ and $4:5:3:1$]. Crystallises from alcohol in yellow scales, melting at 95° . The solution of the hydrochloride in phenol possesses a violet-red colour. By reduction a para-diamine is formed.

Amido-azo-orthoxylylene— $C_6H_3(CH_3)_2N = NC_6H_4(CH_3)_2NH_2$. [$CH_3 : CH_3 : N$ and $N : CH_3 : CH_3 : NH_2 = 3:2:1$ and $4:2:3:1$]. Yellow scales; melting-point 110.5° . From the diamine formed by reduction, orthoxylo-quinone, melting-point 55° was obtained. Hydrochloride soluble in phenol, with a red colour.

Amido-azo-orthoxylylene— $C_6H_3(CH_3)_2N = NC_6H_4(CH_3)_2NH_2$. [$CH_3 : CH_3 : N$ and $N : CH_3 : CH_3 : NH_2 = 4:3:1$ and $6:4:3:1$]. Yellow scales (from alcohol); melting-point 179° . The hydrochloride dissolves in phenol, with a green colour. The diamine gave the characteristic reactions of the compounds of the ortho-series.

Amido-azo-paraxylylene— $C_6H_3(CH_3)_2N = NC_6H_4(CH_3)_2NH_2$. [$CH_3 : CH_3 : N$ and $N : CH_3 : CH_3 : NH_2 = 5:2:1$ and $4:5:2:1$]. Crystallises from alcohol in red scales, melting at 150° . The hydrochloride is red, and dissolves in phenol with a violet-red colour. The diamine crystallises from benzene in beautiful white needles, melting at 146.5° to 147° . It shows all the reactions of the para-diamines, and, by oxidation, yields paraxylo-quinone; melting-point 123° .

None of the above-described amido-azo-xylenes are identical with that obtained by Nietzki. As the diamine and the quinone from amido-azo-paraxylylene agree in all their properties with Nietzki's corresponding compounds, and as the latter were obtained from commercial xylidine, containing meta- and paraxylylene, it appeared very probable that Nietzki's product was a mixed azo-derivative of meta- and paraxylylene. A mixed amido-azo-ameta-paraxylylene— $C_6H_3(CH_3)_2N = NC_6H_4(CH_3)_2NH_2$. [$CH_3 : CH_3 : N$ and $N : CH_3 : CH_3 : NH_2 = 4:2:1$ and $4:5:2:1$ —identical with Nietzki's compound, was prepared by adding to a mixture of 26grms. metaxylidine hydrochloride, and 20grms. paraxylylene, 50cc. of a solution of sodium-nitrite containing 227grms. $NaNO_2$ in 1 litre. A diazo-amido compound, melting at 47° , was formed, which, on keeping, spontaneously changed into the amido-azo compound. This transformation can be completed in a few minutes by heating on the water-bath with 20grms. paraxylylene and 4grms. paraxylylene hydrochloride. This amido-azo-xylene crystallises from alcohol in red scales, melting at 110° to 111° . By reduction it yields meta-xylidine and xylene-paradiazine, melting at 146.5° to 147° , and forming paraxyloquinone.—F. M.

On the Constitution of the Phthalic Acids. E. Nölting. Ber. 18, 2687.

THE author has found that the oxidation of the three xylenes takes place very smoothly when permanganate is employed, and that excellent yields of the three phthalic acids are obtained. As metaxylene forms three isomeric nitro-xylenes, xylidines, and xylenols, orthoxylylene two, and paraxylylene only one of each of these derivatives, isophthalic acid has the position 1, 3; phthalic acid, 1, 2; and terephthalic acid, 1, 4.—F. M.

New Method for the Preparation of Azo-bodies. O. N. Witt. Ber. 18, 2912–2913.

CONSIDERING the unsatisfactory character of the present methods of preparing azo-bodies, the author recommends the following method, which he has found extremely convenient, and of almost universal application. The process depends upon the reduction of the nitro-compound with a solution of sodium-stannite, which is prepared by pouring the calculated quantity of stannous chloride into a cold solution of $NaOH$ in excess. The nitro-

compound is simply heated on a water-bath with the solution, and agitated at intervals. If necessary, it may be previously dissolved in alcohol. Good results were obtained with azo-benzene, *o*- and *p*-azo-toluene, azo-benzenedi-sulphonic acid, and azo-*p*-toluene-di-sulphonic acid; but azo-naphthalene could not be prepared in this way.—A. G. G.

On Indophenols and Indoanilines. R. Möhlau.
Ber. 18, 2913—2918.

THE investigations of Bindschedler, Caro, Nietzki and Witt have shown that the oxidation of mixtures of para-diamines or para-indophenols, on the one hand, with amines or phenols, on the other, gives rise to a great number of colouring matters, some of which belong to the safranin series, others to the indophenol and indoaniline group, and others, again, are unstable intermediate products, which under suitable conditions are capable of being converted into members of one or the other group. That the indophenols and indoanilines are analogously constituted has been long assumed, and the author now brings additional evidence to support this assumption by the conversion of dimethylphenylene green, $(\text{CH}_3)_2\text{N} \cdot \text{C}_6\text{H}_4 \cdot \text{N} : \text{C}_6\text{H}_4 \cdot \text{N}(\text{CH}_3)_2$, into phenol-blue, $(\text{CH}_3)_2\text{N} \cdot \text{C}_6\text{H}_4 \cdot \text{N} : \text{C}_6\text{H}_4 \cdot \text{O}$. This change is produced

by the action of a cold dilute solution of NaOH, dimethylaniline being split off, and the yield of phenol-blue is about 70 per cent. of the theoretical quantity.

By the action of a boiling solution of NaOH on dimethylphenylene-green or phenol-blue the reaction goes further, splitting off a second molecule of dimethylaniline and forming quinonephenolide,

The corresponding naphthylamine compound which should be produced by oxidation of a mixture of dimethyl-*p*-phenylene-diamine and α -naphthylamine is still more unstable, for the chief product of this reaction is α -naphthol-blue, $(\text{CH}_3)_2\text{N} \cdot \text{C}_6\text{H}_4 \cdot \text{N} : \text{C}_{10}\text{H}_7\text{O}$, the naphthylamine compound first formed being decomposed during the reaction, with evolution of NH_3 .

Phenol-blue crystallises from water in steel-blue glistening prisms; from alcohol it forms large bronzy crystals. By cold aqueous acids it is taken up with a blue colour, but on warming, the solution is at once resolved into quinone and dimethyl-*p*-phenylenediamine. The α -naphthol-blue is insoluble in water, but crystallises from alcohol in bluish-violet bronzy crystals. It dissolves in cold acids with a yellow colour, and on allowing the solution to stand it is split up into α -naphthoquinone and dimethyl-*p*-phenylenediamine.—A. G. G.

Commercial Xylidines. W. Staedel and O. Hölz. Ber. 18, 2919—2924.

THE authors have carefully studied the isomeric xylidines occurring in the commercial compound, and have confirmed results already published by Nöling, Witt and Forel (Ber. 18, 2664; this Journal, iv. 741—742), and Nietzki (Ber. 13, 470).

The two isomers, amido-*m*-xylene [$\text{CH}_3 : \text{CH}_3 : \text{NH}_2 = 1 : 3 : 4$] and amido-*p*-xylene were separated by fractional crystallisation of the hydro-bromides; the former crystallises in tables or prisms, the latter in needles. *m*-xylidine gives by the diazo-reaction *m*-xylene and *m*-xylenol. α -*m*-xylidine gives on oxidation by fusion with KOH, *m*-hydroxytoluic acid.

Although the *p*-xylidine could not be prepared in a state of purity (containing an admixture of the *m*-compound), the mixed bases give on oxidation considerable quantities of xyloquinone, indicating the presence of the *p*-compound. Xyloquinol gives with benzoyl chloride dibenzoyl xyloquinol and a corresponding diethyl compound.—J. B. C.

α -Naphthol- β -Sulphonic Acid. A. Claus and M. Knyrim.
Ber. 18, 2924—2930.

ON sulphonating α -naphthol by the usual method, two sulphonic acids are always formed; and these may be separated by the different solubilities of their lead or barium salts. It appears also that a third α -naphtholsulphonic acid is formed and remains dissolved with the α -sulphonic acid, as lime or lead salt. This acid is being investigated by Linke. The barium salt which first crystallises out is the salt of α -naphthol- β -sulphonic acid. The acid is very unstable, and readily decomposes with separation of α -naphthol. To arrive at the constitution of this acid, the authors tried the action of PCl_5 . Instead of the sulphonic chloride, dichloronaphthol and also trichloronaphthol were formed. By the further action of PCl_5 on dichloronaphthol, trichloronaphthalene is produced. On oxidation it is decomposed completely into phthalic acid. For this reason and from its method of formation it is considered to be 1 : 2 : 3 trichloronaphthalene.

By treating dichloronaphthol with chromic and acetic acids, a portion is oxidised to dichloronaphthoquinone, the remainder being either unchanged or oxidised to phthalic acid. As this body is undoubtedly an α -compound, it follows that the sulphonic acid above referred to has the group SO_3H in the β position on the same side of the naphthalene ring as the hydroxyl group of α -naphthol.—J. B. C.

Azo-compounds formed by the Action of Diazo-phenols on β -Naphthylamine. O. Sachs. Ber. 18, 3125—3132.

THE author has prepared the following compounds in order further to investigate the doubtful constitution of the azo- β -derivatives of naphthalene. His results quite agree with those obtained by Lawson (Ber. 18, 796 and 2422; this Journal, iv. 395, and v. 26)—namely, that these bodies behave like diazoamido-compounds with regard to their decomposition by acids into β -naphthylamine, the corresponding phenol and nitrogen; but react on reduction like amido azo-derivatives, giving 1 : 2 naphthylenediamine and the amine.

*Compound from *o*-diazophenol and β -naphthylamine,* $\text{C}_6\text{H}_4(\text{OH}) \cdot \text{N}_3 \cdot \text{C}_{10}\text{H}_7$.—Crystallises from alcohol or acetic acid in fine red needles, from benzene in dark red plates. It melts at 192° — 193° . It dissolves in aqueous or alcoholic NaOH, but is insoluble in water. It gives a mono-acetyl derivative melting at 198° and a mono-benzoyl derivative, melting at 183° . By heating it with HCl at 150° it is split up into β -naphthylamine, pyrocatechol and nitrogen.

Bromine in cold acetic acid solution forms di-bromo- β -naphthylamine and a bromopyrocatechol (?), with evolution of nitrogen. On reduction with acetic acid and zinc dust it gives 1 : 2 naphthylenediamine.

*Compound from *o*-diazophenol and β -naphthylamine,* $\text{C}_6\text{H}_4(\text{OH}) \cdot \text{N}_3 \cdot \text{C}_{10}\text{H}_7$.—Forms flat red prisms of melting-point 191° — 193° , insoluble in water, but easily soluble in benzene and acetic acid. Its mono-acetyl derivative melts at 218° , and its mono-benzoyl derivative at 244° .

By heating with HCl it is resolved into β -naphthylamine, quinol and nitrogen. Bromine gives di-bromo- β -naphthylamine, a brominated quinol and nitrogen; whilst on reduction it yields 1 : 2 naphthylenediamine.

*Compound from *o*-diazophenolmethyl-ether and β -naphthylamine,* $\text{C}_6\text{H}_4(\text{OMe}) \cdot \text{N}_3 \cdot \text{C}_{10}\text{H}_7$.—Crystallises in dark red monoclinic prisms, which melt at 133° and are insoluble in water.

It reacts towards acids, bromine, and reducing agents like the preceding compounds. Its acetyl derivative melts at 199° and its benzoyl derivative at 153° .

—A. G. G.

Constitution of the Azo-compounds of β -Naphthylamine. Th. Zincke. Ber. 18, 3132—3141.

THE author discusses the constitution of the azo-derivatives formed by combining diazo-compounds with β -naphthylamine. Three hypotheses are possible:—(1) That these bodies are true diazo-amido compounds; (2) that they are α -amido-azo derivatives; (3) that they are hydrazimido compounds.

The first hypothesis easily explains their decomposition by acids; and their reduction to naphthylendiamine may be accounted for by assuming that a change into the amido-azo compound takes place during the reduction. However, the fact that different but isomeric bodies are formed by diazotising the β -naphthylamine and combining it with the other amine militates against this hypothesis, for in the formation of diazo-amido compounds it is immaterial which amine is diazotised first.

The second hypothesis: That the compounds are *o*-amido-azo derivatives does not agree with the fact that these bodies are not diazotisable, nor with their behaviour on oxidation, both of which conditions tend to show that they do not contain an NH_2 group.

The third hypothesis, which appears to the author the most likely, involves equal probability for two formulae—viz. :—

of which the latter was proposed by Meldola (*J. Chem. Soc.*, 1884, 107).

These formulae express the analogy of the β -naphthylamine compounds to the corresponding β -naphthol compounds, which latter must have the constitution:

Since they are also formed by the action of phenylhydrazine on β -naphthoquinone.

The third hypothesis is also strongly supported by the fact that on oxidation they give rise to white crystalline azimido compounds, which probably have the constitution:

acid on *o*-phenylenediamine.

The formation of the hydrazimido compounds from a diazo salt and β -naphthylamine can be explained by assuming the intermediate formation of true diazo-amido compounds, $\text{C}_{10}\text{H}_7 - \text{NH} - \text{N} = \text{NR}'$, which by taking up H_2O would form $\text{C}_{10}\text{H}_7 - \text{NH} - \text{N}(\text{OH}) - \text{NHR}'$ or $\text{C}_{10}\text{H}_7 - \text{NH} - \text{NH} - \text{N}(\text{OH})\text{R}'$, and on again eliminating it might give the hydrazimido compound. The decomposition by acids might also be explained as a change inverse to the above, resulting in the formation of the diazo-amido compound, which would then be decomposed.

is prepared by oxidising benzene-azo- β -naphthylamine with CrO_3 in acetic acid. It forms fine white needles, melting at $107-108^\circ$, and sparingly soluble in alcohol and benzene. It is very stable towards reducing agents.

o-Hydroxybenzene-azimidonaphthalene,

an alkaline solution of hydroxy-benzene-azo- β -naphthylamine with lead peroxide. It crystallises from alcohol in white silky needles, which melt at 140° .

p-Hydroxybenzene-azimidonaphthalene,

compound, and forms white needles or thick crystals, of melting-point 199° , sparingly soluble in benzene. Its acetyl derivative forms thin silky plates melting at 165° .

—A. G. G.

On Orthamido-azo Compounds. Th. Zincke. Ber. 18, 3142—3144.

STARTING from the conclusions arrived at in the preceding paper, it seemed probable that the so-called orthamido-azo compounds of the benzene series might be constituted analogously to the β -naphthylamine compounds, and would also prove to be hydrazimido compounds, and not amido-azo compounds. To test this assumption, the author has exposed *o*-amido-azotoluene to oxidation with CrO_3 in acetic acid; and finds that, like the naphthylamine derivatives, it gives a colourless crystalline substance which probably has the constitution—

This azimido compound crystallises in thin plates, which melt at 126° , and is easily soluble in hot alcohol and benzene.—A. G. G.

On the α -Sulphonic Acid of β -Naphthol. Ad. Clans and O. Volz. Ber. 18, 3154—3162.

THIS sulphonic acid, which is formed at a lower temperature than the β -acid, and is usually known as Rumpf's acid, must have the constitution—

since by treatment with PCl_5 the authors obtained from it a mixture of 2:3 chloronaphthol and 2:3 dichloronaphthalene (5 of Clève). This dichloronaphthalene forms small glistening plates, which melt at 61.5° uncorr., and boil at 286° uncorr. On oxidation with CrO_3 , it gives dichloro- α -naphthoquinone—

the anilide of which forms red crystals melting at 202° . The 2:3 chloronaphthol sublimes in fine colourless needles of melting-point 101° uncorr., and boiling-point $307-308^\circ$; is sparingly soluble in water. Rumpf's acid readily forms basic salts; thus the ordinary sodium salt soluble in spirit is $\text{C}_{10}\text{H}_6(\text{ONa})\text{SO}_3\text{Na}$. It crystallises in hygroscopic needles, very soluble in water. This tendency to form basic compounds is probably due to the proximity of the OH and HSO_3 groups. The neutral sodium salt, $\text{C}_{10}\text{H}_6(\text{OH})\text{SO}_3\text{Na}$, forms six-sided plates, sparingly soluble in alcohol, easily soluble in water. The neutral zinc salt, $(\text{C}_{10}\text{H}_7\text{O.SO}_3)_2\text{Zn} + 2\text{H}_2\text{O}$, crystallises from concentrated aqueous solution in needles. The neutral lead salt, $(\text{C}_{10}\text{H}_7\text{O.SO}_3)_2\text{Pb} + 2\frac{1}{2}\text{H}_2\text{O}$, forms colourless glistening rhombohedra, easily soluble in water.

—A. G. G.

On the Constitution of Cochineal. W. Will and H. Leymann. Ber. 18, 3180—3193.

IT has been shown by Hasiwetz and Grabowski that carminic acid is the glucoside of a substance, $\text{C}_{11}\text{H}_{12}\text{O}_5$, which was named carmine-red. The authors have examined the action of bromine upon this body. If carmine-red be dissolved in acetic acid, and treated with bromine, two products are obtained, named provisionally α - and β -bromocarmine. The α -bromocarmine is sparingly soluble in acetic acid, and separates in crystals (yield 10 per cent.), whilst the amorphous β -bromocarmine remains in solution, and is precipitated on adding water (yield 20 per cent.).

α -Bromocarmine, $\text{C}_{10}\text{H}_4\text{Br}_2\text{O}_5$, crystallises in colourless needles, which melt at 248° , and is easily soluble in alkalis.

If it is boiled with strong aqueous KOH it yields α -di-hydroxybromocarmine, $\text{C}_{10}\text{H}_6\text{Br}_2\text{O}_5$. This body forms colourless crystals, melting at 208° . By its behaviour on etherification, it is shown to contain one CO_2H and one phenolic OH group. On oxidation with alkaline KMnO_4 ,

it yields two bodies—an acid and a neutral substance. (a) The acid, $C_9H_6Br_2O_4$, forms colourless crystals of melting-point 244° . By its reactions on methylation, it is proved to contain one OH and one CO_2H , and hence probably has the constitution $C_6(CH_3)(OH)Br_2(CO_2H)(CO_2H)$ or $C_6H(CH_3)(OH)Br_2 \cdot CO_2CO_2H$. (b) The neutral body, $C_9H_4Br_2O_4$, melts at 195° ; and, by its reactions, is shown to be a *dibromohydroxymethylphthalic anhydride*, probably possessing the constitution—

On methylating, it yields the trimethylether of a dibromo-oxyethylphthalic acid. This ether melts at 70° , and on boiling with alcoholic KOH gives the dibromomethoxymethylphthalic acid of melting-point 100° , whose anhydride melts at 144° .

β -Bromocarmine, the second product of the bromination of carmine-red, separates in yellow amorphous flocks on diluting the acetic acid solution with water. It is easily soluble in alcohol, acetic acid, etc., but could not be obtained in a pure state. By boiling with strong KOH it yields β -hydroxybromocarmine, $C_{11}H_8Br_2O_4$. This acid crystallises in glistening yellow needles, which melt at 232° . It is dibasic, and forms red coloured salts. On oxidation with alkaline $KMnO_4$ it yields—

(a) A neutral body, $C_{10}H_6Br_2O_4$, identical with the dibromohydroxymethylphthalic anhydride obtained by oxidation of the α -hydroxybromocarmine, and (b) an acid, $C_{10}H_4Br_2O_6$, which probably has the constitution of a *dibromohydroxycarboxybenzoylformic acid* $C_6(CH_3)Br_2(OH)(CO_2H) \cdot CO_2CO_2H$. This acid crystallises from water in colourless prisms ($+H_2O$), which melt at 230° with evolution of CO_2 .—A. G. G.

Detection of Alkanet Dye. J. Herz. Rep. Anal. Chem. 5, 210—211.

WINES coloured with alkanet tincture yield to ether a yellow colouring matter, while the alkanet red is easily removed by amylie alcohol. In order to separate the alkanet dye from other colouring matters, some almond or olive oil is added, and the amylie alcohol is removed by evaporation on the water-bath. The oil-drops are washed in water, and are seen to be coloured a fine red if alkanet be present. This colour is changed to blue when caustic soda is added in excess, but the blue colour vanishes on the addition of acids. Wines which have been coloured with old alkanet tincture impart to the oil a reddish-violet tint, and the alkaline solution is not blue, but green.—E. G. C.

VI.—DYEING, CALICO PRINTING, PAPER STAINING, AND BLEACHING.

Improvements in the Manufacture or Preparation of Mordants or Fixers for use in Connection with Marking Ink, Pencils, or Points. James Hickisson, London. Eng. Pat. 15,961, December 4, 1884.

THE object of this invention is to manufacture mordants or fixers for use in connection with marking ink, points, or pencils in the form of lozenges, pills, tablets, pastes or powders, or in strip form, the ingredients among which are pyrogallie acid, borax, hyposulphite, soda-carbonate, ammonia, alum, washing soda, or other salts; also gums, French chalk, wax, albumen, collodin, varnish, etc.—T.

Improvements in Writing Ink. Lawrence Hill Armour. Gateshead-on-Tyne. Eng. Pat. 440, January 13, 1885.

THIS invention is to produce an ink which can be washed off paper, or fixed at will. For the former, the inventor uses insoluble pigments suspended in mucilaginous solu-

tions, with the addition of salt, or ammonium chloride, to increase the specific gravity. For the latter, he uses gelatine and chrome alum, or potash bichromate, in the mixture—which is used in non-actinic light—so that while it may be washed off before exposure to actinic light, it may become fixed after exposure adequate to rendering the gelatine insoluble.—T.

Improvements in the Means or Apparatus employed for Dyeing Woolen, Silk, and other Woven or Felted Fabrics and Yarns. Joseph Kettitt. Eng. Pat. 6296, May 22, 1885.

THIS invention differs from the former in that the fabric, after passing through the trough containing the colouring matter, is made to pass over a number of rollers contained in a box into which steam is passed.—E. J. B.

VII.—ACIDS, ALKALIS, AND SALTS.

Action of Hydrochloric Acid on Antimony Sulphide. By J. Lang. Ber. 18, 2714.

THE author finds that antimony sulphide is decomposed by hydrochloric acid of all concentrations, however weak, and at higher temperatures even by pure water, the final state of equilibrium depending on the concentration of the hydrochloric acid, the temperature, and the partial pressure of the resulting sulphuretted hydrogen on the liquid. Antimony chloride dissolved in water acidified with hydrochloric acid, is decomposed by sulphuretted hydrogen, the amount of decomposition depending on the amount of free acid, the temperature, and the pressure of the sulphuretted hydrogen on the liquid. For instance, if a solution of antimony chloride in hydrochloric acid be treated with sulphuretted hydrogen at the ordinary pressure, till no further precipitation occurs, and the clear liquid containing the undecomposed antimony chloride be then decanted and treated with sulphuretted hydrogen at increased pressure, a further precipitation of sulphide will take place.—F. L. T.

On the Composition of "Vitriol Stone" and Colcothar. F. Stolba. Ber. Königl. Böhm. Gesells. 1885.

VITRIOL stone is the important material from which the so-called fuming or Bohemian sulphuric acid is manufactured, and it is obtained from the rock known as vitriol slate ("vitriolschiefer") in the following manner. Large masses of pyritous slate (which belongs to the Silurian formation, and consists of a quartzose matrix containing pyrites, carbon and clay) are exposed to the weathering action of the atmosphere for three years. The products of oxidation so formed are ferrous sulphate and sulphuric acid, which latter acts energetically upon the clay; and, finally, aluminium sulphate and other sulphates are yielded. The ferrous sulphate at first formed becomes, by oxidation ferric sulphate, which, together with the aluminium sulphate, is the principal product of the weathering of the vitriol slate. Ferrous sulphate remains only in small quantities. The next operation is lixiviation of the mass with water, after which the liquor obtained is concentrated to a density of $40^\circ B.$, and finally evaporated in pans until, on cooling, a crystalline cake of vitriol stone is obtained. The vitriol stone is now calcined, in order to remove the greater part of its water. The resulting product, when heated to a very high temperature in clay retorts, yields sulphuric anhydride; and a residue, termed colcothar, remains in the retorts. The composition of vitriol stone and colcothar will be seen from the following analyses:—

Vitriol stone.— Fe_2O_3 —20.07, Al_2O_3 —4.67, FeO —0.64, MnO —traces, CaO —0.14, MgO —0.39, K_2O —0.07, Na_2O —0.05, CuO —0.10, SiO_2 —0.10, P_2O_5 —traces, SO_3 —40.51, As —traces, H_2O —32.58—99.32.
Vitriol stone.— $Fe_2(SO_4)_3$ —50.17, $Al_2(SO_4)_3$ —11.94, $FeSO_4$ —1.35, $MgSO_4$ —1.17, $CaSO_4$ —0.33, $CuSO_4$ —0.20, K_2SO_4 —0.13, Na_2SO_4 —0.11, H_2SO_4 —1.49, MnO , As , and P_2O_5 —traces, SiO_2 —9.10, OH_2 —32.31—99.29.

Colcothar.— Fe_2O_3 —74·62, Al_2O_3 —12·53, MgO —3·23, CaO —0·82, SO_3 —5·17, SiO_2 —1·17, CuO —0·20, H_2O —1·30—99·04.—E. G. C.

Improvements in the Treatment of Certain Residual Liquors from Copper Works and Chlorine Manufacture, to obtain Sulphate of Lime and Oxide of Iron. G. L. Wigg, M. Steele and W. J. Wigg, Runcorn. Eng. Pat. 13,722, October 17, 1884.

THE residual liquor obtained in the precipitation of copper by the wet process, and the residual chloride of calcium from the Weldon process, are mixed in equivalent proportions, when a white bulky precipitate of sulphate of lime is formed. The mass is filter-pressed and washed, and thus forms "Pearl-hardening" in fit condition for use by paper-makers; or, it is furnace-dried at a gentle heat so as to form plaster of paris. The clear filtrate from the precipitate is treated with milk of lime in order to precipitate the iron as ferrous hydrate. The dark green precipitate, which readily forms, is further oxidised by injection of air or chlorine, washed in the filter-press and furnace-dried so as to yield the various shades required.

—S. H.

Improvements in Purifying and Decolourising Crude Nitric Acid, and in Apparatus therefor. J. W. Pratt, Runcorn. Eng. Pat. 14,173, October 27, 1884.

GLASS or earthenware cylinders are arranged in series, and connected by pipes so bent that a current of gas sent through the series will ascend from the bottom of each vessel to the top. The inlet pipe connected to the first vessel is coupled to a horizontal metallic chamber capable of being heated, and this cylinder in its turn is joined to a small coke-tower, which can be moistened with strong vitriol. From the exit of the series a pipe leads to another coke-tower. Between each two vessels is a small chamber into which the current of gas may be switched by means of taps. To bring this apparatus into operation, a quantity of crude nitric acid is placed in each cylinder of the series, and a current of air drawn or forced through the acid. The temperature of the acid must not be below 60° F., or otherwise the air must first be sucked through the warming chamber. The small coke-tower serves to take up the moisture in the air-current. The air in its passage through the acid oxidises, and also carries off mechanically the lower oxides of nitrogen. As the latter portion of nitrogen oxides, carried off from one vessel, would be liable to reabsorption by the next, the current of air is diverted into the small chambers, which are filled with water or oil of vitriol to absorb the oxides of nitrogen carried over. The acid is caused to circulate from the exit to the leader end of the series by reversing the direction of the air-current, forcing or drawing the acid from one vessel to another. The cylinders are fitted with suitable openings for adding any precipitant, the current of air serving to distribute it thoroughly.

—S. H.

Improvements in the Manufacture of Caustic Soda and Potash and By-products therefrom. Sir Francis Bolton, London. Eng. Pat. 14,866, November 11, 1884.

THE invention consists in converting potassium or sodium chloride into caustic potash or soda without the use of sulphuric acid, while at the same time hydrochloric acid is obtained as a by-product. Salt and finely powdered sulphate of barium or strontium are mixed together and heated in a furnace in an atmosphere of steam. Hydrochloric acid is given off; and the resulting mass consists of "a mixture of sodium and barium (or strontium) with an equivalent of oxygen and an equivalent of SO_4 ", along with undecomposed salt and earthy sulphate. On lixiviation a solution of caustic soda is obtained containing more or less chloride of sodium, and a precipitate of sulphate of baryta (or strontia), which can be used over again. The solution of caustic soda is concentrated in the usual manner. The same process may be applied to potassium chloride for the manufacture of caustic potash.—S. H.

Improvements in or relating to the Manufacture of Bisulphite of Calcium, or of other Alkaline Earth. J. W. Kynaston, Liverpool. Eng. Pat. 15,182, Nov. 18, 1884.

SULPHUROUS acid obtained from any source is passed into the bottom of a tower, from the top of which milk of lime of 5 to 6° Tw. descends in a regular stream. The proportion of milk of lime running down the tower must be so regulated that the liquor issuing at the bottom contains a small proportion of sulphurous acid in excess. The mixture of the very insoluble neutral calcium sulphite and water is caught in a lead cistern, when the sulphite quickly settles down, and the supernatant liquor may be run away. The pasty mass is removed from the settler and divided into two equal parts. The one part is transferred to a stone or lead-lined iron vessel, and there mixed with so much water as to contain from $8\frac{1}{2}$ to 9 lb. of calcium sulphite per cubic foot. The other portion is transferred to a stoneware still, constructed similarly to a chlorine still. A pipe from the top of this still leads to the bottom of the first vessel, where it terminates into a distributor. The openings being securely adjusted, hydrochloric acid is run into the still in sufficient quantity to completely decompose the calcium sulphite, and the sulphurous acid is finally driven off by blowing steam into the mixture. The pure sulphurous acid liberated is easily absorbed by the watery mixture of calcium sulphite, and there is obtained a solution of bisulphite of calcium completely saturated and of about 25° Tw.—S. H.

Improvements in or connected with the Manufacture of Sulphite of Calcium. J. W. Kynaston, Liverpool. Eng. Pat. 15,659, November 28, 1884.

A MIXTURE of calcium chloride solution and magnesia, containing also some carbonate of lime, obtained as a residue of an operation hereinafter described, is brought in contact with sulphurous acid, when the following reaction takes place:— $\text{CaCl}_2 + \text{MgO} + \text{SO}_2 = \text{CaSO}_3 + \text{MgCl}_2$. The calcium carbonate present is also completely converted into sulphite, carbon dioxide being liberated. In practice, the sulphurous acid is made to ascend a flag-stone tower, packed with pigeon-holed brick-work, while the mixture of calcium chloride solution, magnesia, and calcium carbonate is run down the tower in such proportion, that from the bottom there runs a mixture of neutral sulphite of calcium, suspended in a solution of magnesium chloride, and containing a slight excess of free sulphurous acid. This mixture is allowed to flow into settling tanks, and when the sulphite of calcium has settled down, the supernatant liquor of magnesium chloride is drawn off and concentrated to a density of from 40 to 45° Tw. A quantity of alkali waste is now taken, and to it, in a closed iron vessel, is added the solution of magnesium chloride. On heating, a decomposition takes place, sulphuretted hydrogen being given off, whilst there remains in the still a mixture of chloride of calcium, magnesia, and carbonate of lime, along with cinders and other matter contained in the original alkali waste. This mixture is passed through a strainer, which retains the cinders and grosser matter, and is then ready to be subjected to the treatment with sulphurous acid, as mentioned above.—S. H.

Improvements in the Manufacture of Acetic Acid, and in Apparatus therefor. E. C. Allan and F. M. Allan, Glasgow. Eng. Pat. 16,636, December 18, 1884.

A CYLINDER A, with a steam-jacket B, is provided with a central shaft D, carrying agitating blades *d*, passing through stuffing boxes in covers C, and driven by gearing E. An acetate, such as acetate of lime, and a mineral acid are introduced through door F in dome E'. Steam is admitted into the jacket B; the acetic vapour formed leaves the apparatus by G, entering the purifier H, where it is washed by any suitable liquids, such as water or acetic acid, containing the carbonates, acetates, oxides of sodium, potassium, magnesium or lead, or heavy petroleum oils, as a solvent for the tar. The purified vapour is condensed in J. The spent material is pushed along

the apparatus by skew blades *d*, and through a discharging door in the opposite end *G*. Steam may be injected

FIG. 2.

FIG. 1.

through valves *k* for further exhausting the material. Various modifications and matters of detail are illustrated in the specification.—C. C. H.

Improvements in the Treatment of Vat-liquor for the Elimination of Sulphides and other Impurities, and in the Recovery and Re-use of the Reagents employed therein. T. D. Owen, Egremont, Cheshire. Eng. Pat. 259, January 8, 1885.

SETTLED vat-liquor of 1·3 sp. gr., is heated nearly to its boiling-point. Oxide of lead, or oxide of lead dissolved in an alkaline solution, is then added in sufficient quantity to decompose the sulphides contained in the solution. The sulphide of lead formed settles very quickly, carrying down the whole of the iron held in solution. The purified liquor is allowed to crystallise, yielding soda crystals containing only from 0·2 to 0·4 per cent. of hydrate. The mother-liquor serves for the manufacture of caustic soda. The sulphide of lead formed in the purification of vat-liquor is roasted at a low red-heat in order to convert it into oxide. After washing with water to free it from alkaline salts, it is ready for re-use. Any loss of lead is made up by the use of sulphate of lead from the vitriol chambers. When contaminated with iron and other impurities by repeated use, the lead compound is treated with strong sulphuric or hydrochloric acid, so as to dissolve out the said impurities.

—S. H.

Improvements in the Treatment of Spent Oxides of Iron and other Substances containing Sulphur, such as Impure Sulphur Precipitate and Impure Melted Sulphur, to obtain Sulphur, and Arsenical Compounds, when the latter are present. J. Robinson, Widnes. Eng. Pat. 497, January 14, 1885.

IN carrying out this invention a different method must be employed, according as the material acted upon contains—1st, sulphur and other substances, but is free from arsenical compounds; or 2nd, sulphur and arsenical compounds; or 3rd, sulphur in combination with other substances, or even sulphur compounds mixed with free sulphur. In the first case, the material to be treated is mixed with soda-waste and lixiviated with a yellow liquor identical in composition with the "yellow liquors" of Mond's sulphur-recovery process. The lixiviation may be assisted by agitation, heat, or pressure, until the liquor has taken up as much sulphur as possible. The solution is then run off and mixed with "over-blown sulphur-liquor," containing a large proportion of sulphites and hyposulphites. It is then decomposed with hydrochloric or any convenient acid; or the solution as run off may be partially oxidised until it has the right composition, so that, on the addition of hydrochloric acid, it will not give off gaseous sulphur compounds. In treating materials consisting of sulphur and arsenical compounds, they are at first lixiviated with only a small portion of the "yellow liquor," for the purpose of extracting the whole or a considerable portion of the arsenic sulphide. If necessary, the same treatment must be repeated. After running off the liquor, the solid residue is melted in a manner usual in the melting of sulphur precipitate; but the solid residue thus freed from arsenical compounds may now also be treated in the manner previously described. Another method of proceeding is, not to eliminate the arsenic until the precipitation of the sulphur takes place. In this case, the sulphur is first dissolved by "yellow liquor," and when the precipitant is added, care is taken not to add a sufficient amount to cause the precipitation of the whole of the sulphur. The arsenic thus remains in solution, and may then be separately precipitated. Lastly, when the sulphur is to be extracted from such substances as spent oxide of iron and the like, the mass is subjected to the action of air and steam, and afterwards lixiviated with "yellow liquor." After dissolving out the sulphur, the oxides of iron may be used again in the purifiers.—S. H.

Improvements in the Production of Chlorine and Hydrochloric Acid from Solutions of Chloride of Calcium. T. Twynam, London. Eng. Pat. 731, Jan. 19, 1885.

TO the solution of calcium chloride previously freed from any dissolved iron by a preliminary precipitation with lime or chalk, a sufficient quantity of milk of lime

is added to form oxychloride of calcium. To cause the formation of the latter, the solution must be heated to at least 50°C ., and the lime constantly agitated in the solution. After some hours the undissolved lime is allowed to settle, together with any sodium chloride which may have crystallised out; the solution being kept hot all the time. The clear liquor is run off and allowed to cool, when oxychloride crystals will readily form. They are separated from the mother-liquor, and dried at a gentle heat, in order to drive off the water of crystallisation. The resulting dry powder consists of an intimate mixture of chloride of calcium and lime. On strongly heating it in a current of air, hydrochloric acid and chlorine are given off, which may be utilised by well-known methods. When superheated steam and air are made to act on the mass, only hydrochloric acid is given off, but the decomposition is more complete. The lime remaining after the decomposition of the chloride may be used for the production of fresh calcium oxychloride.—S. H.

An Improved Method or Process of Purifying Hydrate of Strontium. E. F. Trachsel, London. Eng. Pat. 757, January 19, 1885.

IMPURE hydrate of strontium crystals, containing about 37 per cent. of anhydrous oxide, are dried in a muffle furnace, in order to increase the proportion of anhydrous oxide to about 60 to 70 per cent. By this treatment the sulphide of iron contained in the crystals will be oxidised, and the sulphide of strontium will be changed into hyposulphite, whilst about 2 per cent. of strontium hydrate will be changed into carbonate. The dried crystals are then dissolved in hot water, so that the strontium carbonate precipitates the iron, and the hyposulphite of strontium, which is colourless, remains in the mother-liquor.—S. H.

Improvements in the Manufacture of Sodium Bichromate. W. H. Higgin, Bolton. Eng. Pat. 1723, February 7, 1885.

THE aqueous solution of sodium monochromate obtained from the lixiviating tanks is mixed with the "acid washings" (the production of which is afterwards described), and evaporated to dryness. The residue consists mainly of sodium monochromate, but it also contains more or less sodium bichromate and other sodium salts, according to the composition of the "acid washings." This mass is treated, when cold, with a mineral acid of a certain strength, and in such quantity as to convert the whole of the monochromate present into bichromate. If hydrochloric acid be used, the following equation expresses the reaction:— $2\text{Na}_2\text{CrO}_4 + 2\text{HCl} = \text{Na}_2\text{Cr}_2\text{O}_7 + 2\text{NaCl} + \text{H}_2\text{O}$. Now, if the acid used be of the correct strength, the whole of the sodium bichromate is dissolved, whereas nearly the whole of the sodium chloride is left behind as a finely crystallised powder. The mass is filtered and the filtrate worked up for sodium bichromate in the usual manner. The residue consists of sodium chloride and some chromate salt adhering to it. It is washed with acid of the same kind as is used previously, and the "acid washings" thus formed are employed in the manner mentioned above.—S. H.

Improvements in the Manufacture of Magnesium Chloride. E. K. Muspratt and G. Eschellmann, Widnes. Eng. Pat. 1900, February 11, 1885.

IN a previous specification (No. 5168, 1883) the inventors described the treatment of the chlorate of potash mother-liquors for the manufacture of magnesium chloride. Owing to the presence of a small quantity of magnesium chlorate or hypochlorite, the magnesium chloride solution in boiling is found to dissolve a small quantity of iron from the pan, which colours the magnesium chloride red by formation of iron peroxide. This objectionable colouring of the magnesium chloride may be obviated by adding a sufficient quantity of caustic magnesia, caustic lime, or caustic soda; or by adding a suitable reducing agent such as sulphurous acid, arsenic trioxide, sodium hyposulphite; or lastly, by converting the magnesium

chlorate or hypochlorite into potassium or sodium chlorate or hypochlorite, neither of which will act in small quantities upon the iron of the boiling-down pans. It is also preferable to use cast-iron pans for the purpose of concentrating the liquors.—S. H.

Improvements in obtaining Ammonium Chloride and Cyanogen Compounds. A. French, Bearsden, Dumbartonshire. Eng. Pat. 5945, May 14, 1885.

ANY material containing carbon, nitrogen, sulphur, and common salt or another suitable chloride, is heated in a kiln, air and steam being injected during the heating process. The kiln is worked continuously. The reaction said to take place is expressed by the following equation:— $2\text{NaCl} + \text{H}_2\text{SO}_4 + 3\text{H}_2\text{O} + 2\text{N} + \text{C} = 2\text{NH}_4\text{Cl} + \text{Na}_2\text{SO}_4 + \text{CO}_2$. Nearly the whole of the nitrogen is said to be obtained as ammonium chloride, a small portion of it combining "with carbon and chlorine, hydrogen, carbon monoxide, or sulphurous anhydride to form various cyanogen compounds."—S. H.

Improvements in obtaining Carbonate of Potash by the Leblanc Process. H. Preetz, Stassfurt, Germany. Eng. Pat. 6644, June 1, 1885.

IF sulphate of potash, limestone, and coal are fused together for the manufacture of potassium carbonate, the mixture has to be heated to a very high temperature, which entails considerable losses, owing to a partial volatilisation of the potassium carbonate. The inventor has found that the formation of potassium carbonate takes place at a dull red heat without smelting of the mixture, if one molecule of magnesia be added for each molecule of potassium sulphate in the mixing. The addition of magnesia may be made either in the shape of magnesia, magnesium carbonate, or magnesium sulphate.—S. H.

Improvements in obtaining Sulphuretted Hydrogen from Sulphide of Ammonium. E. W. Parnell and J. Simpson, Liverpool. Eng. Pat. 8440, July 13, 1885.

WHEN Leblanc alkali-waste is treated with ammonium chloride, decomposition takes place, calcium chloride and ammonium sulphide being formed. After separating the latter by distillation, it is treated with ammonium sesquicarbonate, when ammonium monocarbonate is formed in solution with evolution of sulphuretted hydrogen. The ammonium monocarbonate may be again converted into sesquicarbonate by passing carbon dioxide through it; and may be used repeatedly, or it may be passed into the absorbing plant of the ammonia process with sodium chloride and carbon dioxide in the usual manner.—S. H.

A New or Improved Process for obtaining Silicates of the Alkalis and Alkaline Earths from the corresponding Sulphates, together with Sulphurous Acid or Sulphur and Apparatus therefor. W. P. Thompson. From J. and F. Weeren, Berlin. Eng. Pat. 8838, July 22, 1885.

THIS specification, which is accompanied by three diagrams, is not suitable for abstraction.—S. H.

Improvements in the Separation of Sulphuretted Hydrogen from Nitrogen. E. W. Parnell and J. Simpson, Liverpool. Eng. Pat. 7657, August 21, 1885.

THE mixed gases are subjected to the action of a solution containing about 5 per cent. of ammonium monosulphide, whereby sulphuretted hydrogen is absorbed with formation of ammonium sulphhydrate. This latter is decomposed again into sulphuretted hydrogen and ammonium monosulphide by being raised to boiling point, or by being subjected to a partial vacuum. The absorption is carried on in a tower filled with loose stones, at a temperature not above 70°F . The escaping nitrogen is washed with an acid solution to recover

escaping traces of ammonia. The sulphuretted hydrogen, when liberated from the ammonium hydrosulphide, must also go through this process.—A. R. D.

Improvements in or relating to the Manufacture of certain Cyanogen Compounds. Jno. Young, Campsie, Stirling. Eng. Pat. 16,046, August 29, 1885.

THIS invention relates to an improved material for the construction of retorts for the manufacture of cyanogen compounds, by passing nitrogenous gases over carbonaceous matter mixed with an alkali at a high temperature. Material which is non-acid and non-metallic is recommended. Compressed coke or plumbago answers moderately well, but magnesian limestone is the best. The raw limestone is calcined, ground, mixed with tar, moulded, and reburnt, as if for bricks for use in the Gilchrist-Thomas dephosphorising process.

—A. R. D.

The Manufacture of Anhydrous Oxide of Barium. L. Q. Brin and A. Brin, Paris. Eng. Pat. 151, October 5, 1885.

BARIUM nitrate is dried, placed in open crucibles and heated gradually up to 1000 to 1500° C., till the contents of the crucibles become solid, and assume a spongy appearance. The crucibles are then closed and kept at a white heat for four hours. They are then removed to an air-tight chamber, and allowed to cool under a partial vacuum. The result is a very pure anhydrous oxide, peculiarly adapted for use in the process of separating oxygen from nitrogen, described in specification 157 of even date with this.

—A. R. D.

VIII.—GLASS, POTTERY, AND EARTHENWARE.

Improvements in the Manufacture of Tiles and other Objects in Imitation of Majolica Ware. Johann Gottfried Müller, Schöneberg, Berlin. Eng. Pat. 1448, February 2, 1885.

THE inventor imitates majolica by impressing on the enamelled surface of metal plates, relief border lines or outlines of required figures, and introducing and burning within such border lines enamel colour.—T.

IX.—BUILDING MATERIALS, CLAYS, MORTARS AND CEMENTS.

Improvements in the Manufacture of Portland Cement, and in Apparatus to be used in the said Manufacture. W. G. Margetts, Aylesford. Eng. Pat. 15,739, November 29, 1884.

THE mixture of chalk and clay, and sometimes the addition of fuel, as prepared by the wash-mill, is ground, not under stones as hitherto, but between hard iron rollers separated from each other by a space equalling one-sixteenth of an inch, one roller revolving twice the speed of the other. The ground mixture is fed into a pyramidal sieve, rotating about its centre axis at a speed of 150 revolutions per minute; the meshes of the sieve are 900 per square inch. The material passing through is thoroughly intermixed, and the larger particles remaining on the sieve are subsequently ejected by centrifugal force into an outer casing, and carried away to be reground. Unless these particles are separated, imperfect mixture results, and the unground masses of chalk are converted into caustic lime during the final calcination, which gives rise to imperfections or "blows" in the work upon which the cement is used, due to expansion caused by the absorption of carbonic acid by the free caustic lime.—C. C. H.

Improvements in the Manufacture of Portland Cement. W. Smith, Dublin. Eng. Pat. 16,950, December 27, 1884.

THE calcareous sands, which occur on the Irish coasts, are mixed with clay or shale in such proportion that when

calcined the mixture shall contain, calcium oxide 60 to 64 per cent.; silica, 20 to 23 per cent.; alumina and oxide of iron, 6 to 12 per cent. The mixture is ground to a fine powder, made into slurry, dried and calcined.

—C. C. H.

Preparation and Treatment of Wood for the Preservation of the Same, and Apparatus therefor. H. H. Lake, London. From J. H. Young, New York. Eng. Pat. 13,294, November 3, 1885.

THIS specification describes improvements in the Thilmany process for the preservation of timber, and apparatus for more effectually and economically carrying the same into effect. A long riveted copper cylinder is employed, in which the timber is placed on trucks running on rails, and secured therein against floating when the solutions used are admitted into the interior. The wood, after being thus secured, is first heated with steam under pressure, which removes the sap from the fibre; the liquid thus extracted is run out of the saturator, and a solution of barium chloride admitted, and kept under a pressure of 100lb. per square inch, until the pores are fully charged. This is succeeded by a similar treatment with a solution of cupric chloride. The improvements in the apparatus are described at length, and consist of the combination of the various appliances—*e.g.*, air and steam pumps, and tackle for expeditiously handling the masses of timber.—C. C. H.

X.—METALLURGY, Etc.

Selenides from the Andes. By F. Hensler and H. Klingner. Ber. 18, 2556.

THE authors examined some samples of selenides from the Andes, said to be the same as those examined by Pisani (*Compt. Rend.* 88, 391). Their results were, however, quite different. The samples consisted of intimately mixed particles, some of silvery brightness, and others darker and leaden; in some samples also, brass and copper-coloured compounds occurred, but the authors restricted themselves to the analysis of the brighter and darker compounds, separated from each other as fully as possible.

Instead of attacking the substance with chlorine (like Pisani), they fused with a mixture of soda and saltpetre. The results of the examination of two bright samples gave per cent.,

	Ag.	Pb.	Cu.	Co.	Se.
1.	19.20	35.70	12.43	trace.	32.77 = 160.10
2.	27.49	17.10	25.10	0.39	29.54 = 98.92

The results of 1. agree fairly with the formula $(\text{Ag}(\text{Cu Pb})_2\text{Se}_2)_n$, [requiring $\text{Ag} = 18.74$, $\text{Pb} = 35.93$, $\text{Cu} = 11.00$, $\text{Se} = 34.33$] and the results of 2. lie between the formulae $(\text{Ag}_3\text{PbCu})_2\text{Se}_4$, CuSe and $(\text{Ag}_3\text{PbCu}_4)\text{Se}_4$. There are smaller differences in the results of the analyses of two samples of the darker portion.

	Ag.	Cu.	Se.	Bi.	Pb.	Co.
3.	15.81	36.30	46.25	1.61		per cent.
	15.93	36.00	—	—		
4.	19.22	35.41	41.58	3.79		"
	19.16	35.77	41.62	3.45		"

The results of 3. (neglecting 2.3 lead selenide) lead to the formula $\text{Ag}_3\text{Cu}_4\text{Se}_{12}$. Those of 4. (neglecting 4.98 lead selenide) indicate the formula $\text{Ag}_2\text{Cu}_4\text{Se}_6$. The authors consider that the above samples are probably of Argentine rather than Peruvian origin.—F. L. T.

Improvements in Metallic Alloys or Compounds, and in Producing the Same. Arthur George Brookes, London. Eng. Pat. 15,644, November 27, 1884.

ALLOYAGES of metals with metallic sulphides.

—W. G. M.

Improvements in the Reduction of Magnesium. Emil von Püttner, Hohenlohehütte, Prussia. Eng. Pat. 1031, January 24, 1885.

THE magnesic mineral is first so treated that the magnesium is present wholly as oxide; it is then mixed very

intimately with carbonaceous matter, to which may be added oxide of iron, and brought to a strong white heat in retorts; the vaporised metal is condensed and collected, similarly to zinc in the extraction of that metal. A reducing or neutral gas may, with advantage, be passed into the retorts during the distillation. The retorts must be very refractory, and are preferably made from highly aluminous bauxite, or clay, and dolomite, or magnesite. The operation is similar to that of zinc extraction, but requires greater care throughout.

—W. G. M.

An Improved Alloy for Mercurial Gilding. George Lowe and Hymen Levetus, Birmingham. Eng. Pat. 1573, February 5, 1885.

FIVE hundred parts of copper are melted without flux, then 100 parts of cadmium and 0.1 part of aluminium are added, the mixture melted to a running heat, and 100 parts of spelter introduced; the whole is well stirred, and finally 300 parts of corrosive sublimate are added, and the alloy run into an ingot. The colour may be varied by altering the proportions of copper. The metal is of good colour, and takes well the gold amalgam used in mercurial gilding.—W. G. M.

An Improved Method for Dressing or Separating Metalliferous Ores. John Davis, Aberystwith. Eng. Pat. 8765, July 21, 1885.

A PERFORATED plunger actuated by double eccentrics, adjustable for varying the length of the stroke, is placed immediately beneath the fixed sieve or plate through which the fine ore is passing. The ore so passed is delivered through the plunger into a receptacle beneath.

—W. G. M.

A Process for the Utilisation of Waste Liquors or Tank-waste containing Calcium Chloride. J. Webster, Birmingham. Eng. Pat. 12,344, October 16, 1885.

A QUANTITY of calcium chloride liquor is run into a vat, and as much slaked lime or calcium carbonate powder thrown into the vat as will absorb the liquor, and the whole is well stirred. The mass becomes of the consistency of mortar, and is then introduced into a drying furnace, to be dried therein at a temperature gradually raised to 250° F. The dried mass is again immersed in calcium chloride liquor, dried again, and immersed and dried for a third time. It will be found that in these three operations, if carefully carried out, the mass will absorb the greatest possible amount of calcium chloride. The resulting substance is next melted and cast into blocks, in order to be used as a flux in metallurgical operations, such as refining copper, brass, nickel, zinc, tin, aluminium, or other metals or alloys. If it is to be used as a flux in the refinement of iron or in the puddling furnace, it is preferable to add 20 per cent. of peroxide of manganese.—S. H.

XI.—FATS, OILS, AND SOAP MANUFACTURE.

Improvements in the Method of Bleaching or Purifying Oil or Grease. M. Ayrton. Eng. Pat. 2381, February 21, 1885.

ONE cwt. of black oil or brown grease is boiled with 16lb. soda, 12lb. soda ash, 4lb. lime, 2lb. alum, 4lb. starch.—W. L. C.

Improvements in the Chemical treatment of Hydrocarbon, for the purpose of hardening and toughening the same. R. Punshon and S. H. Beckles. Eng. Pat. 1958, February 12, 1885.

FOUR parts of the hydrocarbon—preferably ozokerite—are heated with one part of oxidised oil and 3 per cent. powdered sulphur, to about 200° F. An insulating waterproof and acid-resisting material is thus formed.

—W. L. C.

XII.—PAINTS, VARNISHES, AND RESINS.

A New Nitrocellulose Compound and Products therefrom. W. V. Wilson and J. Storey, Lancaster. Eng. Pat. 491, January 13, 1885.

THE invention relates to the production of a new compound consisting chiefly of nitrocellulose dissolved in acetate of amyl and amyl alcohol.

The amyl alcohol employed is potato spirit or fusel oil.

The proportions given are as follows:—

	(a)	(b)
Nitrocellulose	100 pts.	100 pts.
Amyl acetate	150 pts.	400 pts.
Amyl alcohol	150 pts.	400 pts.

As a varnish this mixture is to be used for decorating wood, leather, fabrics, paper, pictures, photographs, &c., and as a stiff paste for the manufacturer of artificial leather, leather cloth, imitation starched linen—i.e., collars, cuffs, fronts, etc. It may be mixed, if desired, with pigment matter and essential oils. For leather cloth the following mixing is given:—

In addition to the afore-mentioned, take of

Castor or Linseed oil	150 pts.
China clay or pigment	100 pts.
Essential oil (any)	1 pt.
Tannic acid	1 pt.

or if intended for collars, cuffs, &c., add

Castor or Linseed oil	75 pts.
Oxide of zinc	125 pts.
Essential oil	1 pt.

The mixing is to be done in rubber or gutta masticators, and the spreading in the way usual in indiarubber manufacture.—H. A. R.

Improvements in Vulcanized Rubber. W. Swartt, Essex. Eng. Pat. 900, January 23, 1885.

UNSUITED for abstracting.—H. A. R.

Preservative Composition for the Bottoms of Iron Ships. H. J. T. Ford, Cardiff. Eng. Pat. 2014, February 13, 1885.

Coating No. 1 is easily applied, and dries in about one hour. It consists of equal parts of coal-tar, American resin, and red oxide of iron melted together, and mixed while warm with one part of petroleum oil and three parts mineral naphtha. When cold enough, rectified CS₂ is added to make the varnish dry quickly, enough "air slaked lime" to give it a good body, and half-a-gallon of copal tar to the hundredweight. Coating No. 2 is made of equal parts of red lead, red oxide of iron, coal-tar and resin melted together, mixed with petroleum oil two parts, and mineral naphtha two parts, also with "enough CS₂ to envelop same" and four pounds of arsenious acid per hundredweight to destroy parasitic life. Another recipe given for No. 2 is as follows:—Bright red iron oxide ground up with one part Stockholm tar and three parts pine varnish to a thick paste. Then is added one part resin, melted and kept in a liquid state by adding mineral naphtha while cooling, and the whole thinned down by methylated spirit containing three pounds garnet shellac per gallon. Two pounds white arsenic, and two pounds of mercuric oxide are added per hundredweight to prevent marine growths.—H. A. R.

Improvements in Pigments from Iron Ore. W. R. Lake, London. From L. Brown, New York, U.S.A. Eng. Pat. 12,568, October 20, 1885.

THE kind of iron ore chiefly proposed to be used is the kind of magnetite known as "sand-iron ore." It is to be reduced to powder. The powder is hard, durable, non-corrosive and fire-proof. When it is to be used as a paint it may be carried by linseed, fish or other oils, soap-water and glue mixed, solutions of asphalt, bitumen, &c. Supplemental colouring bodies are recommended to be used along with the sand-iron ore, since

owing to its great sp. gr. there is a tendency for it to separate from the oil or other medium.

It is claimed that the above paint acts as a protective coating on iron or steel "by forming thereon a coating of magnetic black oxide of iron."—H. A. R.

XIII.—TANNING, LEATHER, GLUE, AND SIZE.

Improved Means for Waterproofing and Preserving Leather, Cardboard, and similar Materials. P. M. Justice. Eng. Pat. 7223, June 13, 1885.

THE materials are saturated or coated with an essence of the white bark of the birch, with or without tallow or neatsfoot oil, and a small proportion of cerosine.—W. L. C.

XV.—SUGAR, GUMS, STARCHES, Etc.

Galactose and Arabinose by Dilute Acids. M. Conrad and M. Guthzeit. Ber. 18, 2905—2907.

10½GRMS. of galactose heated with 4.85grms. of HCl and 50grms. of water, yielded 1.68grms. of humin bodies, 3.32grms. of lactose, 2.85grms. of acetopropionic acid, and 1.08grms. of formic acid. If galactose be heated with dilute H₂SO₄ of the same percentage as the dilute hydrochloric acid, less acetopropionic and formic acids are produced. 10½grms. of arabinose, heated with the above proportion of dilute HCl, yielded 4.3grms. of humin-bodies, 1.24grms. of acetopropionic acid, and 0.42grms. of formic acid.—A. G. G.

On the Sugars of some of the Cereals and of Germinated Grain. C. O'Sullivan, F.R.S. Proc. Chem. Soc., December, 1885.

BARLEY and wheat are proved to contain sucrose and other non-reducing and reducing fermentable sugars, the nature of which was not accurately determined. Germinated barley contains an increased quantity of sucrose, also maltose, dextrose and levulose. The following table is given to show the change that takes place during germination, the results being calculated in percentages on the dry matter of the grain, the yield of dry malt from dry barley being known:—

	No. 1 BARLEY.		No. 2 BARLEY.	
	Before germination.	After germination.	Before germination.	After germination.
Sucrose	0.9	4.5	1.39	4.5
Maltose		1.2		1.98
Dextrose	1.1	3.1	0.62	1.57
Levulose		0.2		0.71

In highly malted barley the sucrose is high; or if not, its place is taken by the products of its inversion. Maltose also is high in highly malted grain, but occasionally its place is taken by dextrose.

With wheat the results are similar.

As high as 11.4 per cent. sucrose, calculated on the solid matter, has been found in unfermented, unacted-upon malt-wort.

In the discussion which followed the reading of the paper of which the foregoing is an abstract,

Mr. BANISTER said that from experiments made on cereals in their laboratory in 1880, he was able to confirm Mr. O'Sullivan's conclusions as to the presence of sucrose in them. The results obtained were published in the second part of South Kensington Art Handbook on the "Analysis and Adulteration of Foods," page 86. A table is there given of the quantity of sugar found in certain cereals, but as this sugar was not isolated, and only examined chemically and optically, it was said of

it on page 87 of the same book, that "The saccharine body behaves like cane-sugar on being inverted with the same facility, and in not reducing a solution of copper salt." Other references are made to this sugar in different parts of the book, and as it was not crystallised out, it would not have been proper to call it cane-sugar, although it possessed all its properties. The amount of the sugar in the cereals examined was determined: the results were as follow:—Wheat, winter sown, 2.57 per cent.; wheat, spring sown, 2.24; barley, long-eared, 1.34; oats, English, 2.36; maize, 1.94; rye, 4.30; rice, Carolina, 0.38.

The quantity of sugar present in the rye is very remarkable, and especially so as it was found that the samples of rye examined contained no sugar having a reducing action upon copper, while in all the others there was a dextrose body present in greater or less proportion.

In 1871 they had to make a series of experiments on malt-worts, and the changes wrought in them by the addition of different quantities of cane-sugar. During that inquiry, evidence was obtained that there was a saccharine substance in malt possessing most of the properties of cane-sugar, and the results then recorded were worked out on the same lines as we now use for expressing copper reducing power, etc., and accord closely with the most recent observations on the subject.

Mr. O'SULLIVAN said that dextrin or malto-dextrin was certainly present, but in very small amount, in malted grain. He added that the peculiarities in rye were probably largely due to the fact that it was usually cut green, and therefore contained bodies which were not fully elaborated.—W. S.

On the Presence of "Raffinose" in Barley. C. O'Sullivan, F.R.S. Proc. Chem. Soc., December, 1885.

IF the alcoholic extract of barley be evaporated, and the syrup dissolved in the least possible quantity of alcohol, and a little ether added, crystals are obtained, which after recrystallisation form flattened rhombic prisms terminated by a dome parallel to the shorter axis. The composition of these crystals is represented by the formula C₁₈H₃₂O₁₆·5H₂O. They melt in a little water, but are not very soluble in strong alcohol. The substance does not reduce an alkaline cupric solution. The optical activity of the anhydrous body is $[\alpha]_D^{20} = +135$; it is slowly inverted by invertase, but rapidly by a 1 per cent. solution of sulphuric acid; the product of inversion readily reduces an alkaline cupric solution. It is fermented by ordinary yeast. With nitric acid it yields mucic, oxalic, and saccharic acids.—W. S.

XVI.—BREWING, WINES, SPIRITS, Etc.

Improvements in Brewing, etc. E. T. Pemberton, Liverpool. Eng. Pat. 16,043, December 6, 1884.

A COMPOSITION is made by mixing one part of gelatin, dissolved in an equal weight of water, with 16 parts of glucose or uncrystallisable sugar at a temperature of 150° F. For brewing, 30lb. of the composition are added to 40 gallons of water, the solution boiled for one hour, hopped, fermented, and racked in the usual way.—C. C. H.

Improvements in Apparatus for charging Beer or other Liquids with Carbonic Acid or other Gases, and discharging the Liquid from the Containing Vessel. Ivan Levinstein, Manchester. Eng. Pat. 16,868, December 24th, 1884.

THIS is an apparatus for keeping fresh and brisk, as well as reviving Lager or other beers, and consists of an arrangement by which the beer is charged with gas, and at the same time may be forced from the cask as required. With the use of the ordinary vent-peg air is admitted, and the latter portions of the liquor thus become flat. The present invention obviates this imperfection, since the admission of air is replaced by the forcing in of carbonic acid. Drawings are given, illustrating the apparatus.

—G. H. M.

XVII.—CHEMISTRY OF FOODS. SANITARY CHEMISTRY, DISINFECTANTS, Etc.

(A) CHEMISTRY OF FOODS.

Analyses of Various Preparations of Meat. A. Stutzer.
Rep. Anal. Chem. 5, 217—218.

Improved Means and Apparatus for the Preservative Treatment of Meat. P. M. Justice, London. From G. Holgate, Philadelphia. Eng. Pat. 1550, February 4, 1885.

FRESHLY-KILLED meat, instead of being exposed, as heretofore, in refrigerating chambers for a considerable period, is placed in an air-tight chamber, from which the

—E. G. C.

Improved Apparatus for and Method of Preserving the Freshness of Animal and Vegetable Substances. B. H. Thwaite, Birkenhead. Eng. Pat. 16,565, December 17, 1884.

THIS apparatus is constructed by placing a number of air-tight vessels for the reception of the substances to be preserved, round a water-chamber; beneath is a hydrocarbon lamp, the space above which is connected with the preserving-chambers, which in their turn are connected at the top with the water-chamber. The substances being placed in the vessels, the lamp is lighted, and the products of combustion are drawn into the chambers, the air at the same time being removed by using the water-vessel as an aspirator.—C. C. H.

air is afterwards exhausted. This opens the pores of the flesh, instead of closing them, as the usual method of refrigerating does, and hence enables sulphurous anhydride (admitted into the chamber and preferably generated from the condensed gas) to more readily penetrate the interior of the flesh. Carbonic acid gas, generated by any known method, but as dry as possible, is also simultaneously or subsequently passed into the chamber. This method, it is claimed, is not only cheaper, but more effectual, and enables the meat to be kept in the air any length of time without its flavour or quality becoming impaired.—C. C. H.

Milk Ripener and Purifier. J. McKerlie, Glenluce. Eng. Pat. 9170, July 31, 1885.

THE apparatus consists of a shallow, oblong tank, carrying, at the lower part of one of its longest sides, a perforated trough and strainer, beneath which is a metallic corrugated sheet. The solid particles are removed by the strainer, and the passage in a thin film over the corrugated sheet reduces the temperature of the fresh milk to that of the atmosphere, and deprives it of "the animal odour and the carbonic acid gas contained in it."

—C. C. H.

(B) SANITARY CHEMISTRY.

Tarred or Asphalted Cast-iron Water-pipes. W. Thörner. Rep. Anal. Chem., 5, 220.

WHEN blisters or flaws occur in the coating of tar, they are found to promote rapid oxidation of the metal beneath, by exposing surfaces to the action of atmospheric air and moisture, and in this way the water passing through the pipes becomes contaminated with hydrated oxide of iron and fragments of tar. This action is prevented by applying to the cast-iron pipes a perfectly even coating of tar or asphalt, free from flaws and bubbles. With this view, the pipes, after casting and subsequent cooling, are treated with an easily-wetting liquid (such as alcohol, petroleum, petroleum ether, crude benzene, etc.), before being coated with, or, still better, dipped in, the hot tar or asphalt. The result is an even layer, free from flaws and crevices. The liquid used must be one

that will easily mix with the tar or asphalt, and which will afterwards easily evaporate from the protecting layer; if this be the case, there will be no danger of any unpleasant taste or smell being imparted to the water.

—E. G. C.

Improvements in the Manufacture of Materials for use in the Purification by Filtration of Sewage, etc. A. Angell, Southampton. Eng. Pat. 13,818, October 18, 1884.

THE mixture of clay and carbonaceous matter employed in the manufacture of this class of materials is usually exposed to the air for a considerable period, or the water is slowly driven off by a gradual heat prior to calcination. To promote the production of a more porous article, the patentee subjects the wet mass to a high degree of heat at once without the gradual drying. —C. C. H.

Improved Means for the Purification of Water. J. T. Johnson, London. From A. R. Leeds, Hoboken, U.S.A. Eng. Pat. 14,822, November 10, 1884.

WHEN compressed air is brought in contact with water, the co-efficient of absorption of the oxygen increases

bringing water, in motion and under pressure, in contact with compressed air, increased oxidation of the organic impurities resulting. In the figure annexed, D, L, O, R is a bent pipe, provided at the summit of each bend with an automatic escape-valve; water is forced in at E, and compressed air at G; the excess of air and the products of oxidation escape through the valves below which they accumulate; the water does not escape, because the india-rubber ball-valve floats up and closes the exit. The purified water empties into the tank T, after escaping through a valve placed near S, and loaded to the pressure it is desired to maintain in the pipes. The patentee claims—(1) the process of purifying water described; (2) the combination of apparatus; (3) the series of automatic escape-valves. —C. C. H.

Improvements in the Preparation of an Agent for Use in the Treatment of Sewage, etc. J. W. Slater and W. Stevens, London. Eng. Pat. 15,810, Dec. 1, 1884.

THE mineral called Gibbsite, or any aluminous compound containing a considerable proportion of hydrate of alumina, is treated with hydrochloric acid. The

very rapidly. Thus, at ordinary atmospheric pressure, one litre of water dissolves 6.3cc. of air, containing 65 per cent. of nitrogen and 35 per cent. of oxygen; at 8 atmospheres' pressure one litre of water dissolves 50cc. of air, containing 97.3 per cent. of oxygen and 2.7 per cent. of nitrogen. This fact is taken advantage of in the present case, and the purification of water is effected by

acid solution so obtained is used for the precipitation of sewage, such addition being preceded by the neutralisation of the sewage by lime, and the addition of certain proportions of clay and charcoal ground up together. The patentees claim—(1) the preparation of chloride of alumina; (2) its use for sewage precipitation; (3) its use in conjunction with carbon and clay. —C. C. H.

An Improvement in the Purification of Sewage by Precipitation. J. W. Slater and W. Stevens, London. Eng. Pat. 16,592, December 17, 1884.

SPECIFICATION 15,810, December 1, 1884, by the same authors, prescribed a method of precipitation by the addition to the sewage of clay, carbon, and chloride of alumina. The present specification claims the addition of blood, in a fresh state, to the combination before claimed.—C. C. H.

Improvements in Apparatus for Treating Water with Lime, etc. A. Howatson, London. Eng. Pat. 16,705, December 19, 1884.

A TALL, upright tank, having a vertical centre diaphragm reaching nearly to the bottom, is provided at the top of one division with a tray or perforated plate for the reception of the lime or other solid reagent, and at the bottom with a mechanical agitator. The water to be purified is fed in from an overhead tank, and passing down one side of the vessel is mixed with the purifying agent on the tray, and overflows into a second tank of similar construction to the above-described. The downward division of the second, or settling vessel, is provided at its upper part with an agitator, and its bottom is made sloping, leading to a cock for the reception and discharge of the precipitated matter. The purified water overflows at the upper part of the remaining division of the settling tank. The claim is for the apparatus as described.

—C. C. H.

Improvements in the Method of Separating Micro-organisms and their Germs from Liquids. T. R. Shillito, London. From Dr. K. Moller, Brackwede. Eng. Pat. 545, January 14, 1885.

THE liquid is first passed through an ordinary filter to separate mechanical impurities, and afterwards through any suitable fibrous material—e.g., asbestos, slag-wool, paper, etc., compressed until the pores are so small that micro-organisms cannot pass through. This medium may be purified by ignition, treatment with acids, or by heating in vapours at a temperature of from 100 to 160° C.—C. C. H.

Improvements in Purifying and Utilising Sewage. H. Wagner and A. Müller, Berlin. Eng. Pat. 629, January 16, 1885.

THE sewage is defecated with lime, and the sludge separated by filtration of the whole through endless bands of wire cloth and felt. The alkaline filtrate is passed through an apparatus in which a high vacuum is maintained, wherein it is exposed in thin layers in a series of trays. The ammonia given off is absorbed by a continuous stream of sulphuric acid similarly exposed in the same apparatus. The sludge separated may be used, after drying, directly as a manure, or after separation of the fibrous and fatty matter, it may be burned in a gas generator fed by a blast of steam, and the ammonia formed absorbed in a scrubber.—C. C. H.

Improvements in Purifying and Decolorising Sewage and Other Foul Waters, and obtaining a Useful Product therefrom. F. Maxwell Lyte, Putney. Eng. Pat. 900, January 21, 1885.

DEFECATION is effected by the addition to the sewage or water of a soluble aluminate, preferably sodium aluminate in a powdered form. If the water or sewage does not contain sufficient acid to combine with the base and liberate hydroxide of alumina in the mixture, a small quantity either of a mineral acid, an acid salt of alumina, or of potash or soda, may be added. For ordinary sewage from 6 to 7 grains each of commercial sodium aluminate and aluminium sulphate per gallon will be found sufficient.—C. C. H.

Purifying Water, etc., and Apparatus therefor. W. E. Geigel, London. From F. Wolff & Co., Bremen. Eng. Pat. 1144, January 27, 1885.

THE water is percolated through a vessel packed with peat.—C. C. H.

Improvements in the Treatment of Human Excrements, Sewage, etc. C. Lehofer, Bournemouth. Eng. Pat. 5227, April 28, 1885.

UNSUITED for abstracting.—C. C. H.

Improvements in the Preparation of Precipitants for use in the Treatment of Sewage, etc. W. G. B. Bennet, Portswood. Eng. Pat. 6055, May 16, 1885.

"CARBONISED clay" or "carbonised earthy deposit," is reduced to an impalpable powder and treated with sulphuric acid sufficient in quantity to render the iron and aluminous compounds present soluble. The "acidified carbon" is then added to the sewage after the latter has been rendered alkaline.—C. C. H.

Improvements in Method and Apparatus for Dedicating Vegetable and Animal Matter. B. L. Ryder, Chambersburg, Pennsylvania. Eng. Pat. 7352, June 16, 1885.

THE apparatus consists of three flues sloping slightly upwards, rectangular in section, and communicating with each other at alternate ends. The lower flue communicates at one extremity with a desiccating furnace. The fruit or substance to be dried is submitted successively in the three flues to the action of a current of hot air supplied by the furnace. Sulphurous anhydride may be also introduced into the middle or other of the flues to whiten or bleach the desiccated bodies.—C. C. H.

Improvements in the Treatment of Sewage. S. H. James, Tottenham. Eng. Pat. 8084, July 3, 1885.

THE patentee describes, and claims as his improvements—"The mechanical pumping or forcing air through sewage matter (whether precipitated or not) for the purpose of deodorising and purifying the same, and the disposal of the vitiated air and noxious gases evolved in the process by means of pipes or chimnies, discharging the same at a sufficiently high elevation to be unobjectionable."—C. C. H.

Filtering Material for Purifying Water from Nitro-organisms. O. F. Öberg, Stockholm. Eng. Pat. 8282, July 8, 1885.

POROUS carbon blocks are immersed in a boiling solution of an alkaline silicate, dried, and then submerged in a boiling solution of either sulphate of alumina or calcium chloride. The blocks are now dried, after which they are ready for use.—E. G. C.

XX.—FINE CHEMICALS, ALKALOIDS, ESSENCES, AND EXTRACTS.

Action of Hydrogen Peroxide on Antimony Sulphide. By F. Raschig. Ber. 18, 2743.

CLASSEN and Bauer showed (Ber. 16, 1061) that precipitated antimony sulphide treated with hydrogen peroxide and ammonia yields all its sulphur as sulphuric acid, the antimony partly remaining as a white precipitate, and partly going into solution. The author finds that only a small quantity of the antimony remains undissolved as antimonic acid, the bulk going into solution as ammonium antimonate. From this solution, increase of temperature, or addition of alcohol, precipitates ammonium antimonate $\text{NH}_4\text{SbO}_3 + 3\text{H}_2\text{O}$, identical with Frémy's ammoniummetantimonate, $\text{H}_2(\text{NH}_4)\text{Sb}_2\text{O}_7 + 5\text{H}_2\text{O}$. The

author finds the solution of ammonium antimonate convenient for preparing those metallic antimonates that are not precipitated by ammonia.—F. L. T.

On the Constitution of Santonin. S. Cannizzaro. Ber. **18**, 2746–2751.

AFTER a review of the evidence so far obtained regarding the constitution of santonin, the following formula is proposed, as one fairly in accord with the reactions:—

Derivatives of Santonin. V. Villavecchia. Ber. **18**, 2859–2864.

THE author has studied photosantonin acid, discovered by Sestini, and his results confirm the view that it is the agency of light which induces the change in a solution of santonin, forming photosantonin and photosantonin acid.

Photosantonin acid is obtained by exposing an acetic acid solution of santonin to the light. The liquid becomes yellow, and on evaporation is found to contain the new acid. It forms well-defined salts. On exposing an alcoholic solution of santonin to the light, photosantonin is formed, as well as an isomeric body. The author assigns the following constitutional formulae to these bodies: photosantonin acid, $\text{C}_{13}\text{H}_{10}\text{OH} : (\text{CO}_2\text{H})_2$;

The Quantity of Bromine in Sea-Water. E. Berglund. Ber. **18**, 2888–2890.

AS the results obtained by previous observers disagree considerably, the author has made a new series of determinations of the quantity of bromides in sea-water by means of his new method of estimating bromides in presence of chlorides (*Zeit. Anal. Chem.* **24**, 184–195, also 196–199). He finds that the ratio of bromine to 100 parts of chlorine contained in the water only varies in different parts of the world between 330 and 344. This result agrees with the numbers found by Dittmar in the Challenger expedition, but it differs greatly from the results of other observers.—A. G. G.

Artificial Preparation of Cocaine. W. Merck. Ber. **18**, 2952–2955.

THE author prepares cocaine by heating ecgonine with benzoic anhydride and methyl iodide for ten hours in a closed tube to 100°, the following reaction taking place:

A resinous mass is formed containing benzoic ether. After heating with water the ether separates as an oil, and the aqueous solution may be poured off.

After extracting with ether to eliminate benzoic acid, the clear solution is shaken up with AgCl to free it from iodine, and the hydrochloride of the base is precipitated as a crystalline double salt with PtCl₄.

Benzoyllecgonine readily forms cocaine by heating with methyl iodide, and so introducing a methyl group. In order to obtain the homologues of cocaine, the author substituted ethyl iodide, and obtained a brown product, which was purified with difficulty, and contained a new base, having the formula, $\text{C}_{18}\text{H}_{23}\text{NO}_3$, to which the name "cocethyline" has been given. It forms double salts with AuCl₃, HgCl₂, PtCl₄, etc.—J. B. C.

Reduction of Nicotine. A. Liebrecht. Ber. **18**, 2969–2970.

THE author reduced nicotine with sodium and alcohol, and distilled the product with steam—a base distilled

over differing essentially from nicotine. It forms soluble double salts with HgCl₂ and PtCl₄. An analysis of the Pt double salt gave the formula $\text{C}_{16}\text{H}_{26}\text{N}_2$. Six atoms of H have therefore been added, and the body formed probably bears the same relation to piperidine that dipyrindyl does to pyridine. It has therefore been named "dipiperidyl."

Dipyrindyl, $\text{NC}_5\text{H}_4 - \text{C}_5\text{H}_4\text{N}$; dipiperidyl, $\text{NC}_5\text{H}_{10} - \text{C}_5\text{H}_{10}\text{N}$. It is a secondary base, forming a nitroso compound.—J. B. C.

Improvements in the Method of and Apparatus for the Manufacture, Distillation, and Concentration of Alcohol, Hydrocarbons, and Acetic Acids. Donald Daniel Cattanaeh. Eng. Pat. 11,258, Sept. 22, 1885.

THE object of the invention is to provide a process and apparatus by which alcohol and other spirits, of any required degree of purity, may be cheaply produced, and hydrocarbons purified, at any and all times, with an apparatus simple in construction. The essential feature of the invention is the use of pure, dry, heated air in closed vessels in contact with the vapour arising from the materials to be distilled. There are fifteen claims in the patent.—T.

Improvements in the Separation and Obtaining of Oxygen and Nitrogen from Atmospheric Air. L. Q. Brin and A. Brin, Paris. Eng. Pat. 157, Oct. 5, 1885.

ATMOSPHERIC air freed from moisture and carbonic acid is passed through retorts containing heated anhydrous oxide of barium free from carbonates and nitrates. Here the oxygen is absorbed, while the nitrogen passes on to a receiver. When the baryta can absorb no more oxygen the retorts are disconnected with the air supply and the nitrogen receiver, and are connected with the oxygen holder. Increased heat is now applied to the retorts, and a partial vacuum created in the oxygen-holder. This causes the liberation of the absorbed oxygen, leaving the baryta ready for a repetition of the process.—A. R. D.

XXII.—GENERAL ANALYTICAL CHEMISTRY.

Production of Sulphuretted Hydrogen free from Arsenic. F. Gerhard. Rep. Anal. Chem. **5**, 214–215.

THE author strongly recommends the method of preparing this gas consisting in warming a solution of magnesium sulphhydrate, which has been made by passing ordinary sulphuretted hydrogen into water containing magnesia in suspension; he calls attention, however, to the disadvantage that this mode of preparing the solution of the magnesium salt is troublesome and tedious, and he states that a much simpler plan is to mix the alkaline or calcium hydrosulphide with an equivalent amount of a solution of magnesium sulphate or chloride. The result is a solution containing magnesium hydrosulphide, together with the alkaline or alkaline earthy salt. This solution, when warmed over a gas-burner or placed in a vessel standing in hot water, liberates sulphuretted hydrogen, freely and evenly.—E. G. C.

Determination of Small Quantities of Sodium Chloride in the Presence of Potassium Chloride. F. Röttger and H. Precht. Ber. **18**, 2076–2078.

THE method is based upon the greater solubility of sodium chloride in 90 to 95 per cent. alcohol as compared with that of potassium chloride: 100 parts of 90 per cent. alcohol at 15° C. dissolving 0.345 NaCl and 0.073 KCl.

The finely-powdered sample (20grms.) of mixed salt is extracted with sufficient alcohol, $\frac{1}{2}$ cc. of 10 per cent. potassium carbonate solution added to the extract to precipitate any magnesium chloride, which is then filtered off, the filtrate evaporated in a platinum dish to dryness, gently ignited and weighed. The KCl is determined in this, in the usual way with platinum chloride and the NaCl calculated as difference. The result is accurate to $\frac{1}{1000}$ th per cent. The amount of platinum chloride necessary for the determination by this method

is very much less than that required by the older processes, an important point where many analyses have to be made.—T. L. B.

Separation of Iron from Aluminium. M. Hlinski and G. v. Knorre. Ber. 18, 2728.

THE facts on which the separation depends are:—

Nitroso- β -naphthol produces in solutions of ferric salts a bulky dark-brown precipitate of the composition $(C_{10}H_6ON_2O)_3Fe$, soluble in mineral acids and in glacial acetic acid, but insoluble in 50 per cent. acetic acid solution, and being quantitatively separated in the cold from solutions to which not more than 10 per cent. of hydrochloric acid solution (sp. gr. 1.12) have been added.

From solutions containing ferrous salts nitroso- β -naphthol separates the iron as a dark-green precipitate in the absence of free mineral acid.

No compound of alumina with nitroso- β -naphthol has as yet been obtained.

To perform the analysis:—To the previously concentrated solution containing the iron (ferric) and aluminium as chlorides or sulphates, ammonia is added till a slight permanent precipitate is produced, which is dissolved by a few drops of hydrochloric acid. Then to the cold liquid an equal bulk of 50 per cent. acetic acid is added with stirring, and an excess of nitroso- β -naphthol (dissolved in 50 per cent. acetic acid).

After standing six to eight hours the liquid is filtered, washed firstly with 50 per cent. acetic acid and then with cold water. After drying, the filter containing the precipitate is placed in a tared porcelain crucible, crystallised oxalic acid approximately equal in bulk to the precipitate is added, the filter closed, and the whole gently heated. The method of incineration recommended is to leave the loosely-covered crucible on a piece of asbestos board heated by a small flame till no more fumes are given off, then to ignite strongly, with access of air till all carbon is burnt. Weigh as ferric oxide. It is easy to incinerate the precipitate in this way without loss. If no oxalic acid is added the precipitate decrepitates.

The check analyses are good.

The separation cannot be performed in presence of phosphoric acid.

Nitroso- β -naphthol is a very delicate test for ferrous salts, giving a fine green colouration with water containing only three milligrammes of iron per litre.—F. L. T.

New Method for the Determination of Alumina. K. J. Bayer. Zeits. Anal. Chem. 24, 542, p.

NORMAL soda solution is added to a given quantity of alum solution, until the precipitate at first formed has completely redissolved. An alkaline alumina solution is thus obtained, containing the sulphates of sodium and potassium. Litmus tincture is added, and the mixture is exactly titrated with normal sulphuric acid. The number of cc. required will be considerably smaller than the number of cc. of normal soda already used, according to the equation—

The difference between the normal sulphuric acid used in the titration and the normal soda at first added gives the quantity of soda corresponding to the sulphuric acid required by the alumina present.—E. G. C.

Separation of Zinc from Cadmium by Electrolysis. S. Eliasberg. Zeits. Anal. Chem. 24, 548, p.

THE author has tried the process described by A. Iver (*Bull. Soc. Chim. de Paris*, 34, 18), according to which a solution of the acetates or sulphates of the metals is treated with 2–3 grms. of sodium acetate and a few drops of acetic acid, and then, after warming, decomposed with the aid of two Daniell's elements; and he finds that, unless the solution is kept warm during the entire period of the electrolytic action, the cadmium is not completely

separated. It is also remarked by him that two Bunsen's cells, with a resistance interposed, and producing a current capable of liberating 0.5–0.6 cc. of oxy-hydrogen per minute, are preferable to two Daniell's elements, the current from which is not powerful enough for the required purpose. Other batteries may of course be used. The fluid to be electrolysed should not measure more than 90 cc., and the operation must, according to the author, occupy not less than six hours. This is considerably longer than the time mentioned by A. Iver. Some results obtained by the author are here given:—

TAKEN.		CALCULATED.	FOUND.

—E. G. C.

On the Decomposition of Silicates by means of Alkaline Carbonates. F. Stolba. Ber. Königl. Böhm. Gesells. October, 1885.

THE author finds that rapid solution of the separated alkaline silicates, and their removal from the platinum crucible, are promoted in an extraordinary degree by the addition to the completely fused mass of from half its volume to its own volume of sodium chloride. The covered platinum crucible is now heated until the mixture is quite fluid. Treatment with hot water, and exceedingly rapid solution, follow; hydrochloric acid is next added, and the evaporation to dryness is proceeded with in the usual manner.—E. G. C.

New Books.

FRESenius' QUANTITATIVE ANALYSIS. Vol. II. Part II. Translated by Chas. E. GROVES, F.R.S. J. & A. Churchill, 11 New Burlington Street, London.

THE appearance of Part I. of the translation of Fresenius' important work by Mr. Groves, F.R.S., we announced in this Journal, vol. iv. p. 138. The issue of Part II. will consequently be hailed with satisfaction. The pamphlet form is continued, 8vo size, and the price of each part is 2s. 6d. The subject of Organic Chemical Analysis is continued and completed on page 112. In this branch, however, are included the following: Deduction of Empirical Formulae, pp. 101–104; Deduction of Rational Formulae, pp. 104–112. A special part now follows, devoted to the Analysis of Waters, I.; Analysis of some Technical Products and Minerals, with Processes for Estimating their Commercial Value, II. Under the latter heading the subject of *Acidimetry* is first taken up and continued to page 192, where Part II. ends with the *Preparation of Normal Oxalic Acid*, the consideration of which will be continued in Part III.

THE GAS ENGINEER'S POCKET ALMANACK AND LIGHTING TABLE FOR THE YEAR 1886. Issued by WILLIAM SUGG & Co. Limited, Engineers, Vincent Street, Westminster, S.W. : 1 and 2, Grand Hotel Buildings, Charing Cross, S.W. : Crystal Palace, Sydenham ; and Paris.

SMALL 8vo volume—pocket-book form, bound in morocco leather, gilt, and fastened with elastic band, price 2s. 6d. The book commences with a Calendar for 1886 ; then follows an article on the Lighting and Extinguishing Street Lamps, etc., which contains a table giving the Monthly Totals of Lamplight for the yearly totals of 4300, 3940, and 3836 hours. A useful Diary for gas managers now appears, so that besides the varieties of coals used in the mixtures for the retorts, there can be entered up the makes of gas for each day of the week, the volumes in stock in the holders, and the amounts sent out. A Glossary of Terms in most frequent use in connection with Gas Works, with their equivalents in the French and German, is the next item, and this is followed by the NOTIFICATION OF THE METROPOLITAN GAS REFEREES as to the times and modes of testing for illuminating power. Well-illustrated descriptions of all the apparatus recommended by the Gas Referes, with tables for reference, etc., are given. Blank pages for Memoranda, divided for the months of the year, are usefully arranged next in order, and then, all the items required to be entered up and summarised each month in a Gas Works are printed and ruled off on alternate double pages, blanks being left only for the figures, so as to make the whole a complete and universally useful little reference book for gas managers. The little work concludes with a few tables of equivalent weights, measures, and prices, etc., and finally, with some Interpolation Curve tables which have been calculated and arranged by Mr. Jas. T. Brown. These have the effect of rendering Sugg's Lighting Table applicable to all parts of the world.

CHEMICAL EQUILIBRIUM, THE RESULT OF THE DISSIPATION OF ENERGY. By G. D. LIVEING, M.A., F.R.S. Deighton, Bell & Co. Cambridge ; George Bell & Sons, London. 1885.

8vo VOLUME, bound in cloth, containing 97 pages of subject matter, lithographic plate showing the position of certain lines in the spectrum, and photographic plate showing lines, when the light of the electric arc is dispersed by prisms of caespar. A general idea may be formed of the mode of treatment of the subject from the following abstract of the table of Contents :—Chapter I. *Introductory*. II. Equilibrium in Dissociation. III. Termination of Reactions. IV. The Nascent State. V. The Passage from one state of Equilibrium to another. VI. Theoretical View of the Nature of Chemical Combination.

Monthly Patent List.

I.—GENERAL PLANT, APPARATUS, AND MACHINERY.

APPLICATIONS.

1885.

15686 W. M. Fraser, Glasgow. Improvements in furnaces and apparatus for burning liquid fuel. Complete specification. December 21

15709 A. Attwood, London. Improvements in continuous power presses for making cartridges or pellets of gunpowder, line, coffee, tea, and other concrete substances. Dec. 21

15713 S. H. Johnson and C. C. Hutchinson, London. Improvements in subsidence apparatus. December 21

15762 A. G. Martin, London. Method of and apparatus for obtaining superheated steam at a constant temperature. August 5

15531 H. Podger and G. Bryant, London. Improvements in the make and construction of apparatus for heating air. December 21

15865 W. R. Jones, Westminster. Improvements in duplex furnaces specially adapted for burning breeze and inferior fuel. Complete specification. December 21

15873 F. Bruggemann and L. Donkers, London. Improvement in or applicable to internally-heated boilers for the purpose of economising fuel. Complete specification. Dec. 21

15598 J. T. Griffin, London—Communicated by J. W. Hatch, United States. Improvements in and relating to furnaces, in apparatus to be used therewith, and in utilising solid and gaseous fuel therein. December 24

15599 Cordner, Allen & Co., London—Communicated by P. Gaillot, France. Improvements in apparatus for separating liquid from solid matters suspended therein. December 29

15972 N. H. Humphrys, Westminster. Improvements in apparatus for preventing explosions of steam boilers and the regulation of fluids under pressure or exhaust. December 29

16014 J. Laidlaw and A. J. Liversedge, Glasgow. Improvements in the construction of centrifugal machines, otherwise known as hydro-extractors. December 30

16035 J. N. Longden, London. A construction of crucibles, retorts, and other vessels that are subjected to high temperatures. December 30

16036 J. N. Longden, London. Construction of furnaces for treatment of ores and metals. December 30

16037 J. N. Longden, London. Apparatus for condensation of furnace fumes. December 30

16065 G. A. Bishop, Coatbridge, N.B. Improved firebricks, retorts, crucibles, and other fire-resisting articles of a similar nature. December 31

1886.

96 S. Fox, London. Improvements in apparatus for generating or producing and utilising gases. January 1

119 W. Begg, Manchester. Improvements in the construction of furnaces. January 5

183 F. White, London. Improvements in means employed for consuming smoke passing from the grates of furnaces and preventing the emission of smoke from furnaces. January 5

221 J. P. Marsh, Liverpool. Improved self-acting valve, applicable for use in chemical works, to prevent the return of liquor when force or pressure is exerted in an opposite direction. January 6

266 R. Wainwright and W. Wainwright, London. Improvements in the construction of furnaces for effecting the consumption of smoke. January 7

298 C. T. Colebrook, London. Improvements in or applicable to self feeding and smoke-consuming furnaces. January 7

382 J. Watson, London. Improvements in apparatus for burning oils or liquid fuel in steam-boilers. January 9

397 H. Stockheim, London. Improvements relating to filtration and apparatus therefor. January 9

403 J. L. Sampson and J. Hart, London. Improvements in furnaces. January 9

404 J. L. Sampson and J. Hart, London. Improvements in apparatus for feeding fuel to furnaces. January 9

406 H. C. Swinnerton Dyer, London. Improvements in regenerative furnaces. January 9

599 N. Evans, Liverpool. Improvements in and in connection with apparatus for supplying air to furnaces and combustion chambers, more particularly of steam generators. Complete specification. January 11

672 A. Neubecker, London. Improvements in refrigerating machinery or apparatus. January 15

713 B. Spencer and J. Driver, Halifax. A method of and apparatus for condensing smoke in steam boilers, and utilising the products for heating and other purposes. January 16

902 T. Curtis, Glasgow. Improvements in the modes and means, or apparatus for, refrigerating or cooling liquids. January 20

907 A. Howatson, London. Improved methods of arranging plates or appliances in vessels used for separating solid impurities from water or other liquids. January 20

COMPLETE SPECIFICATIONS ACCEPTED.*

1885.

1510 G. Fletcher and W. P. Abell. Centrifugal machines for drying crystalline or granular substances. December 22

3133 J. Inray—Communicated by H. Remaury and F. Valton. Manufacture and application of materials for lining furnaces and metallurgical vessels or utensils. January 8

14491 W. T. Cortin. Stop valves for use with chemical fluids. January 15

15252 P. M. Justice—Communicated by C. Dietzsch. Process and furnaces for burning limestone or lime, and similar materials. January 12

II.—FUEL, GAS, AND LIGHT.

APPLICATIONS.

1885.

15574 F. Wright, London. Improvements in apparatus for determining the illuminating power of gas. December 18

* The dates given are the dates of the Official Journals in which acceptances of the Complete Specifications are advertised. Specifications thus advertised are open to inspection at the Patent Office immediately, and to opposition within two months of the said dates.

- 15614 W. Menzies, Newcastle-on-Tyne. Improvements in artificial fuel for marine and other steam boilers. Dec. 19
 15706 E. Blass, London. Improvements in water-gas apparatus for distillation of the fresh fuel. December 21
 15759 S. W. Allen and G. Breilit, London. Improvements in the process of making compressed fuel from small coal and pitch or other similar materials. December 22
 15768 A. M. Clark, London—Communicated by J. S. Lenz, United States. Improved process for manufacturing illuminating gas. December 22
 15780 H. H. Lake, London—Communicated by H. K. Flagler, United States. Improvements relating to the utilisation of fuel in a comminuted condition, and to apparatus therefor. December 22
 15803 S. Banner, Liverpool. Improvements in or appertaining to the manufacture of mineral illuminating oil. Dec. 23
 15832 S. Chandler, S. Chandler, jun., and J. Chandler, London. Improvements in regenerative gas lamps or lanterns. December 24
 15850 J. Lewis, London. An improved application to gas burners for increasing the illuminating power of gas enriched with other gaseous compounds. December 28
 16052 W. Young, Glasgow. Improvements in the purification of coal-gas and in apparatus therefor, the same being in part applicable for the preparation of caustic ammonia solutions. December 31
 16081 H. H. Blackmore, London. An improved method and apparatus for producing gas from petroleum or other oils or chemicals. December 31

1886.

- 128 B. H. Thwaite, Liverpool. Improvements in methods of supplying air to gas or other burners for illuminating purposes. January 5
 176 H. J. Haddan, London—Communicated by J. T. Wethered, United States. Improvements in apparatus for the manufacture of illuminating gas. January 5
 197 G. F. Redfern, London—Communicated by J. Lacoste, France. An apparatus for indicating the escape of illuminating and other gas. January 5
 292 A. Gutensohn, London. Improvements in the manufacture of artificial fuel and fire-lighters. January 7
 251 C. Wells, London. An improved candle. January 8
 352 C. Wells, London. An improved multiple-wick candle. January 8
 389 C. Wells, London. Improvements in candles. Jan. 9
 451 J. Parkes, Birmingham. Improvements in apparatus for enriching illuminating gas. Complete specification. January 12
 495 S. Banner, Liverpool. Improvements in the manufacture or blending of burning oils. January 12
 603 S. Banner, Liverpool. Improvements in the manufacture, blending, or treatment of certain mineral hydrocarbons or compounds of hydrocarbons. January 14

COMPLETE SPECIFICATIONS ACCEPTED.

1885.

- 2104 J. F. Braidwood. Means and apparatus for closing the mouths of gas-retorts, etc. January 8
 2679 W. Boggett. Apparatus for burning oils and fats with or without admixture of gas for the production of light and heat. December 22
 3323 T. Alexander, S. Alexander, and R. Paterson. Apparatus for making oil-gas. January 22
 3908 A. T. D. Berrington. Method of regenerating waste gases. January 15
 15686 W. M. Fraser. Furnaces and apparatus for burning liquid fuel. January 22

III.—DESTRUCTIVE DISTILLATION, TAR PRODUCTS, Etc.

COMPLETE SPECIFICATION ACCEPTED.

1885.

- 2693 F. J. Rowan. Distilling and obtaining useful products from coal or other carbonaceous mineral, and apparatus therefor. January 15

IV.—COLOURING MATTERS AND DYES.

APPLICATIONS.

1885.

- 15632 W. Smith, London. A new vegetable blue dye. December 19
 15716 C. Rudolph and O. Gurke, London. Improvements in the manufacture of colouring matters. December 21
 15775 H. H. Lake, London—Communicated by The Schoellkopf Aniline and Chemical Company, United States. Improvements in and relating to colouring matters. Complete specification. December 22
 15781 H. H. Lake, London—Communicated by The Schoellkopf Aniline and Chemical Company, United States. Improvements in and relating to colouring matters. Complete specification. December 22

1886.

- 38 B. J. Cresson, London. Improvements in dyeing and printing aniline black and in the solutions used therefor. January 1

- 43 C. D. Abel, London—Communicated by C. Roth, Germany. Improvements in the production of colouring matters or dyestuffs. January 1
 510 A. Brunstein, London. Improved method and apparatus for obtaining alizarin oil from oleaginous seeds. January 12
 765 J. V. Johnson, London—Communicated by A. Faust, Germany. Improvements in the manufacture or production of para- and ortho-nitrobenzylalcohol and para- and ortho-nitrobenzyldehyde. January 18

COMPLETE SPECIFICATIONS ACCEPTED.

1885.

- 3119 H. J. Haddan—Communicated by the Farbenfabriken vormals F. Bayer & Co. Blue and violet colouring matters. December 25
 14232 E. Elsaesser. Manufacture of azo-dyestuffs or colouring matters. December 29
 11802 A. L. Hughes, J. Bartley, and F. Best. Improvements in laundry blue. January 5

V.—TEXTILES: COTTON, WOOL, SILK, Etc.

APPLICATIONS.

1885.

- 15705 C. E. Mey, London. Process for coating paper and woven fabrics with waterproof material, said process being specially applicable in the manufacture or treatment of shirt collars, cuffs, and fronts. December 21
 15717 W. R. Lake, London—Communicated by F. E. J. Dubar, France. An improved textile fabric. December 21
 15809 T. R. Shillito, London—Communicated by R. Baur, Germany. An improved process for the treatment of flax, hemp, china grass, and similar vegetable fibrous materials in order to obtain fibres. December 23
 15871 E. Edwards, London—Communicated by T. G. Meili, Germany. An improved process or system for the manufacture of waste cotton yarns. December 24
 15906 T. F. Wiley, Bradford. Improvements in the method or process of treating textile fabrics to render them waterproof. Complete specification. December 28
 15947 F. Candy, London. Improvements in the preparation of fuller's earth for use in manufactures. December 28
 15948 F. Candy, London. Improvements in the treatment and utilisation of a certain kind of clay. December 28

1886.

- 322 W. H. Maitland, London. Improvements in treating wool in order to destroy burrs or other vegetable substances mixed therewith. January 8
 564 O. Chemin, London. Improvements in the treatment of animal fibres or mixed fabrics, to remove vegetable matters therefrom. January 13

VI.—DYEING, CALICO PRINTING, PAPER STAINING, AND BLEACHING.

APPLICATIONS.

1885.

- 15637 J. Menzies, Glasgow. An improved oleaginous liquid to be used for batching fibrous substances and in dyeing operations. December 19
 15761 H. J. Haddan, London—Communicated by J. F. Meyer and G. Klinkenberg, Germany. Apparatus for dyeing felt and woven fabrics. December 22

1886.

- 38 B. J. Cresson, London. Improvements in dyeing and printing aniline black and in the solutions used therefor. January 1
 83 W. Bracewell, Brinscall, Lancashire. Improvements in apparatus for kiers used in bleaching. January 4
 597 R. H. Ainsworth and E. B. Manby, London. Improvements in machinery to be used in bleaching quilts and other heavy or light fabrics and yarns, by the "Thompson" or other analogous processes, which are also applicable to dyeing purposes. January 11
 617 W. Stewart, Glasgow. Improvements in calico printing machines. January 11

COMPLETE SPECIFICATIONS ACCEPTED.

1885.

- 3219 J. A. Ashwell. Process of dyeing hosiery, etc., and apparatus therefor. December 29
 1148 J. Farmer—Partly communicated by A. Lalauze. Apparatus for washing, chloring, scouring, etc., woven fabrics. January 12

VII.—ACIDS, ALKALIS, AND SALTS.

APPLICATIONS.

1885.

- 15661 T. R. Shillito, London—Communicated by E. Hanisch and M. Schroeder, Prussia. An improved process for separating substances from phosphate of lime. December 19

15836 N. M. Henderson, Broxburn, N.B. Improvements in apparatus for distilling ammonia. December 24
 16007 A. Whittle, Swinton, Lancashire. The utilisation of a chemical refuse, known as vat refuse or gas lime. December 30

1886.

46 E. W. Parnell and J. Simpson, Liverpool. Improvements in the production of pure carbonic acid gas. January 2
 47 E. W. Parnell and J. Simpson, Liverpool. Improvements in the manufacture of carbonate of soda, with production of sulphuretted hydrogen. January 2
 48 C. Wigg, Liverpool. Improvements in the manufacture of bicarbonate of soda, and in apparatus therefor. January 2
 63 G. Jarmay, London. Improvements in separating the ammonium chloride from liquors obtained in the manufacture of soda by the ammonia process. January 2
 65 L. Mond, London. Improvements in obtaining ammonia and hydrochloric acid from ammonium chloride. January 2
 66 L. Mond, London. Improvements in obtaining ammonia and chlorine from ammonium chloride. January 2
 150 T. Robinson, Glasgow. Improvements in the manufacture of alum and sulphate of alumina. January 5
 180 John Addie and James Addie, Glasgow. An improved process for the production of sulphurous acid gas. January 5
 159 J. E. Bennett, London. Improvements in the treatment of metallic chlorides for the production and extraction of metallic bases. January 5
 227 N. Matheson and J. Hawliczek, London. Improvements in the manufacture of carbonate of soda and soda ash. January 6
 480 W. Wilson, London. Improvements in the purification of acetate of lime. January 12
 676 A. Deckers and R. Tamine, Liverpool. Improvements in the treatment of crude phosphate of lime. January 15
 715 W. B. Giles and A. Shearer, London. Improvements in the manufacture of phosphoric acid. January 16
 719 A. Oschenbruck, London. Improved method for the manufacture of anhydrous ammonia, and for the utilisation thereof for the production of cold or of work, or of both cold and work together. January 16
 872 P. Thomas, London. Improvements in apparatus for producing sulphurous acid in solution. January 20
 903 F. B. Hawes, London. A new or improved manufacture of sulphuric acid from certain sulphides. January 20

COMPLETE SPECIFICATIONS ACCEPTED.

1885.

2578 H. Simon—Communicated by the Berlin Anhaltische Maschinenbau-Actien Gesellschaft, Germany. Apparatus for the distillation of ammonia from ammoniacal liquors, and for the treatment of the resulting ammoniacal vapours. January 8
 3098 J. Wilson. Decomposing liquors containing chloride of magnesium. December 29
 4290 W. J. Chrystal. Manufacture of chromates and bichromates. January 19
 5882 A. Boake and F. G. A. Roberts. Manufacture of potassium sulphates. December 29
 14780 L. E. L. J. B. Régi and L. M. C. Folie-Desjardins. Process and apparatus for the manufacture of sulphuret of carbon, and alkaline chlorides and silicates. January 22

VIII.—GLASS, POTTERY, AND EARTHENWARE.

APPLICATIONS.

1885.

15743 H. Standen, Harlesden. The manufacture of glass for sanitary and other purposes. December 22
 16098 M. Ritter von Spann, London. Improvements in the manufacture of decorated glass-ware. December 31

1886.

297 W. Boulton and J. Davenport, London. An improved method and means of neutralising the oils used in colour printing earthen or china-ware. January 7
 801 J. Scott, South Sunderland. An improved and cheaper method in the manufacturing of rough plate glass by steam power, and improvement in kiln. January 19
 805 W. Jakes and W. J. Kershaw, Birmingham. Improvements in the ornamentation of glass articles and sheet or plate glass. Complete specification. January 19
 855 J. Wildigg, Hanley. The ornamenting of pottery and porcelain by a new method of applying "runners." January 20
 892 W. de Morgan, London. Improvements in means for transferring designs to articles of pottery ware. January 29
 965 A. Wilkinson, London. Improved methods of operating upon glass for producing ornamental or other effects. January 21

COMPLETE SPECIFICATIONS ACCEPTED.

1885.

2310 J. Northwood. Decorating in various designs threaded glass articles in course of manufacture. December 29

8585 W. W. Boulton. Manufacture of glass or glass articles decorated with stripes. December 25
 14628 W. H. Hales. Machinery for moulding pottery-ware. January 8

IX.—BUILDING MATERIALS, CLAYS, MORTARS, AND CEMENTS.

APPLICATIONS.

1885.

15751 W. Joy, London. Improvements in the method of charging cement kilns. December 22
 15760 J. Longden, Sheffield. Improvements in ganister cement. December 22

1886.

31 W. Joy, London. Improvements in the utilisation of the waste heat from cement kilns and lime kilns. January 1
 116 J. Ferguson, Carlisle. Improved material for fire-proofing internal surfaces of buildings. January 5
 117 H. Peters, London. Improvements in the manufacture of Portland cement. January 11
 517 J. Bidwell and A. Bidwell, London. An improved cement or composition for various purposes. January 13
 809 J. Hadfield and J. Trippett, Sheffield. Improvements in treating and finishing the surfaces of asphalt, concrete and cement, when employed for floors, roads, pathways, and the like purposes; and apparatus and appliances for carrying the same into effect. January 19
 847 N. Snyer, London—Communicated by The Agalite Fibre Co., United States. Improvements in the preparation of plastic materials or compounds. January 19

COMPLETE SPECIFICATIONS ACCEPTED.

1885.

1778 J. Tomlinson. Manufacture of plaster or cement. December 29
 2742 R. E. Goolden. Improved plastic compounds. January 19
 2775 W. J. A. Donald. Refractory materials and bricks, etc., suitable for lining furnaces and converters. December 29
 3916 E. Ormerod and W. C. Horne. Rendering cements luminous and damp-proof. January 12
 5187 A. W. Lake—Communicated by T. Hyatt. Improvements in illuminating tiles, and constructions made therefrom. December 29
 5188 A. W. Lake—Communicated by T. Hyatt. Improvements in illuminating combination tiles. December 29
 13639 W. Keller. Manufacture of cement or mortar. Jan. 1
 14061 H. Mathey. Manufacture of cement and lime. Jan. 15

X.—METALLURGY, MINING, Etc.

APPLICATIONS.

1885.

15901 J. R. Turnock, Loughor, S. Wales. Multiplex tin-plates, terne-plates, and other coated sheets. December 28
 15555 A. M. Clark—Communicated by H. Hannett, France. Improvements in purifying metals. December 18
 15813 E. G. Colton, London—Communicated by A. F. Wendt, New York. Improved process and apparatus for treating "flux-skunnings," resulting from the process of galvanising. December 23
 15814 M. Vesenmayer, London. Improvements in the method of collecting finely-divided gold and float gold, and in apparatus therefor. December 23
 15988 W. Elmore, A. S. Elmore, and H. Barrett, London. Improvements in the means of, and apparatus for the extraction of metals from their ores, particularly in the treatment of "blue-stone," and similar complex ores; and for electrolytically refining copper, and for the manufacture of sulphuric acid by electrolytic action. December 29
 16036 J. N. Longden, London. Construction of furnaces for treatment of ores and metals. December 30

1886.

27 F. A. Herbertz, London. Improvements in cupola smelting furnaces. January 1
 123 A. Montupet, London. Improvements in cupola furnaces. January 1
 159 J. E. Bennett, London. Improvements in the treatment of metallic chlorides for the production and extraction of metallic bases. January 5
 219 M. P. Hayes, London. Improvements in the casting of steel, and in moulds and apparatus connected therewith. January 6
 434 A. J. Maskrey and W. Jones, Glasgow. Improvements in or relating to the process of tinning plates and manufactured articles. January 11
 482 W. W. Popplewell, London—Communicated by A. F. Wendt, United States. Improvements in the method of, and apparatus for, separating and purifying metals and alloys of metals. January 12
 566 R. Hadfield, London. Improvements in the production and treatment of steel. January 13
 612 A. R. Sawyer, Stoke-on-Trent. An improvement in the mode of blasting or rending coal, ironstone, rock, and other mineral substances. January 15

618 T. Archer, jun., London. An improved implement for coal hewing and mining purposes. January 15
 939 J. Howie, Glasgow. An improved process for disintegrating or pulverising auriferous, stanniferous, and other ores. January 21
 918 A. Bobrownicki, London. Improvements in the treatment of phosphoretic slag. January 21

COMPLETE SPECIFICATIONS ACCEPTED.

1885.

1360 T. V. Hughes and F. W. Harbord. Manufacture of basic plug-bottoms and bricks for the interior of Bessemer converters. December 22
 2835 J. C. Ridley. Pots for melting and desilverising lead. January 8
 3923 H. Wiggin, H. A. Wiggin, A. S. Johnstone, and W. W. Wiggin. Manufacture of nickel and cobalt. January 15
 3271 A. Davy. Apparatus for making steel by the Bessemer process. January 1
 6596 A. Davy. Apparatus for making steel by the Bessemer process. January 1
 6729 W. P. Thompson—Communicated by A. Kurzwehnart and E. Bertrand. Casting iron or steel ingots. December 29
 8039 H. Bain. Tinning and finishing tin andterne plates, and machinery therefor. January 12
 11921 W. P. Thompson—Communicated by C. Huscagvel. Producing malleable iron or steel direct from the ore, and apparatus therefor. January 5

XI.—FATS, OILS, AND SOAP MANUFACTURE

APPLICATIONS.

1885.

16033 J. L. Sabunje, London. Improvement in the manufacture of medical soap and tonic for hair-washing. December 30

1886.

125 T. Goodman, London—Communicated by A. Vignat and V. Capoul, France. Improvements in the manufacture of tallow for industrial and alimentary purposes. January 4
 326 C. D. Abel, London—Communicated by The Fabrik Chemischer Produkte Actien Gesellschaft, Germany. Method for the preparation of lanolin and anhydrous lanolin from the waste liquors of wool-washing establishments, and from commercial wool fat. January 8
 419 J. Y. Johnson, London—Communicated by C. L. Baillard, France. Improvements in the preparation or treatment of oils for use in treating wool, in the manufacture of soap and lubricants as mordants for dyeing, and for analogous uses. January 11
 510 A. Brunstein, London. Improved method and apparatus for obtaining alizarin oil from oleaginous seeds. January 12

COMPLETE SPECIFICATIONS ACCEPTED.

1885.

2990 E. Green and E. Needham. Washing and cleansing fluid. January 15
 4090 G. Payne. Refining glycerine. January 15
 6667 J. H. Ashwell. Treating or utilising soap suds. December 22

XII.—PAINTS, VARNISHES, AND RESINS.

APPLICATIONS.

1885.

15752 P. Lawson, Glasgow. A new or improved anti-corrosive and anti-fouling enamel paint. December 22

1886.

571 W. Hamilton, London. An improved metallic compound or composition for the preservation or protection of ships, structures, and surfaces generally. January 13

COMPLETE SPECIFICATIONS ACCEPTED.

1885.

12891 A. W. Anderson. Apparatus for facilitating the dissolution of oxide of lead and other substances for making lead salts for the manufacture of white lead, etc. January 8
 15171 C. D. Abel—Communicated by E. Schaal. Manufacture of turpentine from the resins of conifers. January 19

XIII.—TANNING, LEATHER, GLUE AND SIZE.

APPLICATIONS.

1885.

15565 W. P. Thompson, Liverpool—Communicated by G. E. Muth, Germany. Improvements in the preparation of soluble casein-albumenates, and in the application of the same for sizing, finishing, or varnishing paper, textile fabrics, wood, metal, and the like. December 18

1886.

938 J. L. Wade, Glasgow. Improvements in size for stiffening and finishing textile fabrics, yarns, and threads. Jan. 21

XV.—SUGAR, STARCHES, GUMS, Etc.

APPLICATIONS.

1885.

15828 S. M. Lille, Philadelphia, U.S. Improvements in process and apparatus for drying bone-black. Complete specification. December 23
 15897 M. P. W. Boulton, B. E. R. Newlands, and E. Perrett, London. A process for revivifying spent charcoal. Dec. 21
 15985 A. W. G. Adey, London. Improvements in the treatment of indiarubber waste. December 29
 16053 J. Schwartz, jun., London. Improvements in the manufacture of sugar. December 31

1886.

508 W. R. Lake, London—Communicated by W. T. Jebb, United States. Improvements in the manufacture of starch. Complete specification. January 12
 951 M. Mackay, London. The manufacture of a new material to be used as a substitute for gutta-percha and ebonite. January 21

COMPLETE SPECIFICATIONS ACCEPTED.

1885.

1540 G. Fletcher and W. P. Abell. Centrifugal machines for drying sugar, etc. December 22
 1541 G. Fletcher. Centrifugal machines. January 8
 1542 G. Fletcher. Sugar-cane mills. December 22
 2738 G. Buchanan. Machinery or apparatus for treating sugar-cane. December 25
 7745 C. W. Guy. Sugar-cane crushing mills. January 22

XVI.—BREWING, WINES, SPIRITS, Etc.

APPLICATIONS.

1885.

15598 H. J. Worssam, London. Strainer-plates for hop-backs and mash-tuns for breweries. December 18

1886.

783 J. A. F. Bang and M. C. A. Ruffin, Paris. An improved process and apparatus for the purification of alcohol. Jan. 18

COMPLETE SPECIFICATION ACCEPTED.

1885.

5833 A. Boake and F. G. A. Roberts. Improvements in brewing. January 12

XVII.—CHEMISTRY OF FOODS, SANITARY CHEMISTRY, DISINFECTANTS, Etc.

APPLICATIONS.

1885.

(A) *CHEMISTRY OF FOODS.*

15599 V. Tribuillet and E. Husson, London. Improvements in the preservation of alimentary substances, and in apparatus therefor. Dec. 18
 15721 A. F. Besnier and F. L. Corbiere, London. An improved manufacture of chocolate. December 21

(B) *SANITARY CHEMISTRY.*

15864 F. R. Conder, London. Improvements in the use and application of iron compounds, such as sulphate of iron, for the purification of water, and for other sanitary and curative purposes. December 24
 15895 C. D. Abel, London—Communicated by M. M. Rotten, Germany. Improved apparatus for purifying the effluent waters or liquids from factories, sewers, and the like. Dec. 24
 16060 J. H. Kidd, Wrexham. The complete purification of sewage from organic matter. December 31

(C) *DISINFECTANTS.*

15868 F. Candy and N. Frere, London. An improved closet-pan disinfectant. December 21

1886.

(B) *SANITARY CHEMISTRY.*

10 V. L. E. Miller, London. The drying of sewage, Jan. 1
 520 J. C. Bothams, Fisherton Anger, Wilts. Improvements in the arrangement and construction of apparatus for extracting sewage, sludge, or other semi-solid matter from tanks or places where it subsides or is precipitated. Jan. 13

572 E. R. Hordley, London. Improved Method of treating solid sewage matter, and the production of a substance therefrom suitable for manure. Jan. 13
 900 A. G. Salamon, London. Improvements in the purification of water and other fluids. January 29

COMPLETE SPECIFICATIONS ACCEPTED.

1885.

(A) CHEMISTRY OF FOODS.

11233 J. E. Taylor—Communicated by W. Peacock. Preservation of fruit. December 22

(B) SANITARY CHEMISTRY.

2352 J. G. Lorrain. Filtration and purification of fluids, and oxidation of matters suspended or dissolved therein. Dec. 22
 2728 C. Price and H. Cleave. Filtration of sewage and apparatus therefor. January 12
 2885 W. P. B. Mainwaring and J. Edmunds. Purification of sewage and water containing organic matter. December 29

(C)—DISINFECTANTS.

 13151 E. G. Colton—Communicated by F. Haenichen, O. Haenichen, and O. Seebass. Neutralising the residual magnetism in electro-magnets. December 22

XIX.—PAPER, PASTEBOARD, Etc.

APPLICATIONS.

1886.

836 W. S. Hodgkinson and F. Lee, London. An improved paper suitable for bank notes, cheques, and the like. January 19

COMPLETE SPECIFICATIONS ACCEPTED.

1885.

4569 A. McDougall. Boilers for conversion of woody or other fibres into pulp for the manufacture of paper, etc. January 22
 9602 L. A. Groth—Communicated by F. Kurtz. Pulping or rag engine, used in the manufacture of paper. January 8

XX.—FINE CHEMICALS, ALKALOIDS, ESSENCES, AND EXTRACTS.

APPLICATIONS.

1886.

596 C. Fahlberg and A. List, London. New compounds of organic alkaloids and saccharine, and method of producing the same. January 14
 629 T. Gladysz, London. Improvements in the manufacture of tartaric acid. January 11

XXI.—EXPLOSIVES, MATCHES, Etc.

APPLICATIONS.

1885.

15691 The Patent Oxonite Co., Limited, and R. Punshon, London. Improvements in safety blasting cartridges and detonators. Complete specification. December 21
 15635 S. H. Emmens, London. Improvements in projectiles for operations of war. December 21
 15636 S. H. Emmens, London. Improvements in smokeless gunpowders. December 21
 15637 S. H. Emmens, London. Improvements in the composition and manufacture of explosive substances. December 21
 15958 G. Bloem, London. An improved shell for fulminate and dynamite detonators, and for fulminating compounds in general. Complete specification. December 29

1886.

112 H. A. Schlund and A. Martin, London. Improvements in percussion fuses. January 4
 758 W. D. Borland, London. Improvements in explosive substances, and absorbent materials therefor. January 18

COMPLETE SPECIFICATIONS ACCEPTED.

1885.

3671 S. Russell. Electric cartridges, and electric primers therefor. January 22
 15089 A. M. Clark—Communicated by E. Turpin. A new explosive; processes of preparing and using the same; and shell charged therewith. January 15

XXII.—GENERAL ANALYTICAL CHEMISTRY.

APPLICATIONS.

1885.

15678 W. E. Heys, Manchester—Communicated by E. Becker, United States. Improvements in and relating to chemical or analytical balances. Complete specification. December 21

THE JOURNAL

OF THE

Society of Chemical Industry:

A MONTHLY RECORD

FOR ALL INTERESTED IN CHEMICAL MANUFACTURES.

No. 2.—VOL. V.

FEBRUARY 27, 1886.

Non-Members 30/- per annum; Members
21/- per Set; Single Copies 2.6.

The Society of Chemical Industry.

Past Presidents:

Sir H. E. Roscoe, M.P., LL.D., V.P.R.S.	1881—1882.
Sir Frederick Abel, C.B., D.C.L., F.R.S.	1882—1883.
Walter Weldon, F.R.S.	1883—1884.
W. H. Perkin, Ph.D., F.R.S.	1884—1885.

COUNCIL FOR YEAR ENDING JULY, 1886.

President: E. K. Muspratt.

Vice-Presidents:

Sir F. A. Abel, C.B., D.C.L., F.R.S.	Peter Griess, Ph.D., F.R.S.
Sir I. Lowthian Bell, Bart., F.R.S.	W. H. Perkin, Ph.D., F.R.S.
Alexander M. Chance.	Sir H. E. Roscoe, M.P., LL.D., V.P.R.S.
Prof. James Dewar, F.R.S.	John Spiller.
James Duncan.	E. C. C. Stanford.
David Gamble.	J. C. Stevenson, M.P.

Ordinary Members of Council:

R. Forbes Carpenter.	S. A. Sadler, Ph.D.
Henry Doulton.	Sir Bernhard Samuelson, Bart., M.P.
John Evans, D.C.L., F.R.S.	Sir Chas. Tennant, Bart., M.P.
Ivan Levinstein.	Prof. W. A. Tilden, F.R.S.
Rudolph Messel, Ph.D.	John Williams.
R. E. R. Newlands.	
Thomas Royle.	

With Sixteen Chairmen and Secretaries of Sections.

Honorary Treasurer:

E. Rider Cook, M.P., East London Soapworks, Bow, E.

Honorary Foreign Secretary:

Ludwig Mond, 20, Avenue Road, Regent's Park, N.W.

General Secretary: Charles G. Cresswell.

Offices:

Palace Chambers, 9, Bridge Street, Westminster, S.W.

NOTICE.

The supply of copies of the Journal for January, 1882, being now exhausted, the Secretary would be glad to receive communications from members possessing extra copies of that number, in good condition, with a view to purchase.

Should sufficient applications for complete sets be received, the number will be reprinted.

CHANGES OF ADDRESS.

J. Anderson, 1/o Coatbridge; Glengarnock Ironworks, Glengarnock, Ayrshire.
R. Barr, 1/o Kerrsland Terrace; 44, Granby Terrace, Hillhead, Glasgow.
Wm. Boyd, Tharsis Co.'s Works, East Moors (not East Woods), Cardiff.
J. T. Brown, 1/o Battersea; 46, Kilmaine Road, Fulham, S.W.
C. Burgmann (address for Journals), 11, Warwick Gardens, Kensington, W.
A. G. Hyard, 1/o Brunswick Terrace; 70, Fisher Street, Canning Town, E.
W. J. Diddin, Metropolitan Board of Works, and Mayfield, Grange Road, Sutton, Surrey.
S. Figgis, Wildwoods, North End, Hampstead, N.W., and 6, Mincing Lane, E.C.
C. H. Gimmingham, 1/o Newcastle; Stamford House, Northumberland Park, Tottenham, N.
A. Haacke, 1/o Lime Street; 111, Fenchurch Street, London, E.C.
W. D. Herman, 1/o Cropper's Hill; West Park, St. Helen's.
C. Hodgson, 1/o Barrow; High House, Eppleby, Darlington.
F. Krohn, 1/o Hampstead; 16, Taurus Strasse, Wiesbaden, Germany.
L. A. Lewis, 1/o Poplar; Ireton Lodge, Cromwell Avenue, London, N.W.
R. F. Macfarlane, 1/o Taibach; Rio Tinto Co., Limited, Cwm Avon, Port Talbot, South Wales.
T. S. Marsh, 1/o Connah's Quay; Phospho Guano Co., Limited, Seacombe, Cheshire.
P. Naef, 1/o Widnes; Uetikon, Zurich, Switzerland.
W. G. O'Beirne (address for Journals), North British Chem. Co., Clydebank, N.B.
H. Peile, 1/o Middleton-one-Row; Shotley Bridge, County Durham.
J. W. Pratt, 1/o Runcorn; 20, Westbourne Terrace, Kelvin-side, Glasgow.
Wm. Scott, 1/o North Woolwich; Vryheid's Lust Sugar Estate, East Coast, Demerara.
F. Seudder, 1/o Normanton; 26, Devonshire Street, Ardwick, Manchester.
H. H. Slater, 1/o Hornsey Road; Clifton Villa, Brading, Isle of Wight.
D. V. Stuart, 1/o Albert Chem. Works; Eagle Chem. Works, Clayton, Manchester.
S. M. Thomas, 1/o Bristol; 143, Cannon Street, London, S.W.
A. J. Watts, 1/o Agua Preta; 45, Caixa, Pernambuco, Brazil.
S. G. Webb, 1/o Montpelier Road; 6, Wellington Road, St. Mary's Road, Peckham, S.E.
G. Whewell, 1/o Regent Chambers; 15, Exchange Street, Blackburn.
O. N. Witt, 1/o Mannheim; 33, Lindenallee, Westend, Charlottenburg, Berlin.
J. Williams, 1/o Buckingham Street; 63 Warwick Gardens, Kensington, W.
J. C. Wright, 1/o Waterside Street; 11, Hill Street, Irvine, N.B.

ERRATUM.

In lists of members and new members in the January issue, "G. H. Allibon's" name was written "G. H. Allison," in error.

LIST OF MEMBERS ELECTED FEBRUARY 23rd, 1886.

- J. B. Adam, 172, Leith Walk, Edinburgh, paint and varnish manufacturer.
- J. M. T. Anderson, Explosives Co., Limited, Stowmarket, manager Guncoiton Works.
- J. W. Bennie, Guaranteed Manure Works, Cubitt Town, E., analyst and manager.
- T. T. Best, Sliema, Victoria Park, Wavertree, Liverpool, science student.
- E. R. Blundstone, 10, Wellington Mansions, North Bank, Regent's Park, N.W.
- W. Briggs, Springfield Terrace, Arbroath, N.B., manufacturing chemist.
- A. Cheeseman, Bedford Road Brewery, Luton, Beds., brewer.
- W. Cheeseman, Westminster Brewery, London, S.W., brewer.
- H. G. D. Clark, Brewery, Twickenham, Middlesex, brewer.
- C. S. A. Collins, 11, St. Stephen's Street, Salford, Manchester, chemist.
- Meurig, L. Davies, 77, Everton Terrace, Everton, Liverpool, chemist.
- W. P. Dreafer, 8, Albert Square, Clapham Road, S.W., science student.
- W. H. Eaton, Chemical Works, Lostock Hall, near Preston, chemist.
- G. W. Elkins, 123, Walnut Street, Philadelphia, Pa., U.S.A., coal-tar products manufacturer.
- F. Fallowfield, Clayton-le-Moors, near Accrington, calico printer.
- Harold H. Fries, 6, Mohrenstrasse, Berlin, W., student and manufacturer.
- J. Galt, Glenpark Oil Works, East Nelson Street, Glasgow, oil refiner.
- W. J. Gascoyne, Ph.D., Dept. of Agriculture, Richmond, Va., U.S.A., analyst.
- J. Grime, Rose Bank Cottage, Busby, near Glasgow, calico printer.
- Hugh, F. W. Gwatkin, 19, Wellington Terrace, Stratford-on-Avon, brewer.
- Bertram H. Hart, The Elms, Old Charlton, Kent, S.E., chemist.
- C. L. Higgins, Rainhill, Lancashire, and c/o Messrs. Muspratt, Widnes, chemist.
- Masuo Ikuta, Univ. Lab., 33, Georgenstrasse, Berlin, N.W., student.
- J. Jack, jun., 371, Duke Street, Glasgow, oil distiller.
- E. H. Keiser, Bryn Mawr College, Bryn Mawr, Pa., U.S.A., professor of chemistry.
- K. Kenyon, Printworks, Handforth, near Manchester, manager.
- J. B. Lober, 3409, Race Street, Philadelphia, Pa., U.S.A., manufacturer of coal-tar products.
- J. Longmore, Hillside, Brentwood, Essex, chemist.
- Hugh R. Mill, Scottish Marine Station, Granton, Edinburgh, chemist and physicist.
- J. Neilson, 107, John Street, Glasgow, manufacturer.
- G. J. Newman, jun., Laurel Bank, Wilmslow, Cheshire, chemist.
- Harry Newton, Park Green, Macclesfield, silk dyer.
- J. Obermeyer, Saal 16, Georgenstrasse 36, Berlin, N.W., chem. student.
- Albert Pages, 34, Boulevard Henri IV., Paris, industrial chemist.
- H. Peachey, North Street, Chichester, brewer.
- Carl F. Pfeiffer, 1, Sutherland Road, West Ealing, technical student.
- J. Roscow, Fair View, Littleborough, near Manchester, print works manager.
- H. Schellhaas, 54, Navigation Road, Northwich, mechanical engineer.
- L. H. Schubart, Chem. Lab., Georgenstrasse 25, Berlin, N.W., chemist.
- R. D. Silva, 26, Rue de la Harpe, Paris, professor of chemistry.
- Geo. F. Smith, Cromwell Lodge, Putney Hill, S.W., chairman Amsterdam Water Company.
- A. Timmins, Stanley Villas, Runcorn, civil engineer.
- A. M. Todd, Nottawa, St. Joseph Co., Mich., U.S.A., manufacturing chemist.
- P. H. Walsh, Weston Salt and Manure Works, Weston, Stafford, chemist.
- Thos. Wilde, Spring Place, Rhinaderin, Newport, Monmouthshire, forge manager.
- Frank H. Wilson, Desoto Alkali Co., Limited, Widnes, analyst.
- A. B. Winstone, 100 Shoe Lane, London, E.C., chemical manufacturer.
- E. T. Wood, Brinscote, Chorley, Lancashire.
- Jao. Young, Olive Villa, Cemetery Road, Hanley, gas engineer.
- W. Zinkeisen, B.Sc., 1, Woodside Place, Glasgow, chemist.

London Section.

CHEMICAL SOCIETY'S ROOMS, BURLINGTON HOUSE.

Chairman: David Howard.

Committee:

Sir F. A. Abel.	R. Messel.
H. E. Armstrong.	R. E. L. Newlands.
W. Lant Carpenter.	R. Redwood.
W. Crowder.	T. Royle.
C. Graham.	John Spiller.
S. Hall.	G. C. Trewby.
A. K. Huntington.	J. Williams.

Local Sec. and Treasurer: Thos. Tyrer,
Garden Wharf, Church Road, Battersea, S.W.

MEETINGS, SESSION 1885-86.—First Monday in each month (unless otherwise indicated).

ORDINARY MEETINGS.

First Monday in the Month, at 8 p.m.

March 1.—Mr. Boverton Redwood, F.I.C.—“Viscosimetry.”
March 15.—Mr. T. B. Lightfoot, M.I.C.E., M.I.M.E.—“Ice Making—and Cooling Machinery;” and the Discussion on Mr. J. W. Westmoreland's Paper, which appears below.

April 5.—Professor Unwin, M.I.C.E.—“The Principles and Methods of Testing Cementing Materials.” This meeting will be held in the Central Institute, City and Guilds of London Institute, Exhibition Road, South Kensington.

May 3.—Mr. A. G. Salamon—“Purification of Water,” Messrs. Macnab and Beckett—“The Treatment of Water for Technical Purposes.”

June 7.—Dr. Meymott Tidy—“Chemical Treatment of Sewage.”

July.—Annual Meeting at Liverpool.
Notices of papers and communications for the meetings to be sent to the Local Secretary.

Meeting held Monday, February 1, 1886.

MR. D. HOWARD IN THE CHAIR.

THE DETERMINATION AND VALUATION OF COPPER IN ORES AND PRODUCTS FOR COMMERCIAL PURPOSES, WITH SOME REMARKS ON THE ASSAY OF GOLD IN BAR COPPER.

BY JAMES W. WESTMORELAND, F.I.C.,

Associate of the Royal School of Mines, London; Metallurgical Chemist, and Assayer, Leeds.

ALTHOUGH many members of the Society of Chemical Industry are engaged in the smelting and refining of copper from furnace material, and also in the extraction of copper from the burnt cinders of cupreous pyrites which have been used in the manufacture of sulphuric acid; and, although the smelting of copper and the manufacture of alkali are frequently conducted by the same firms in contiguous works, with the exception of a few remarks made in the discussions on “Uniform Methods of Analysis,” regarding the inaccuracy of the Cornish method of assaying copper ores (*Journ. Soc. Chem. Ind.*, 1884), and a paper by Dr. Watson, “On the Influence of Some Constituents on the Specific Gravity of Commercial Copper” (*Journ. Soc. Chem. Ind.* 1883, p. 153), no communications regarding the processes used in copper smelting in England, or on the methods used for the determination and valuation of copper have been made to the Society, and on referring to scientific and technical journals, the same lack of information is apparent.

Having been engaged for some years in the examination of copper ores, and being cognisant of the serious discrepancies in the analyses and assays which frequently occur, it seemed to the writer that a paper

on the subject would be of interest to the members generally.

Although for commercial purposes the valuation of copper ores, mattes, precipitates, and bar coppers (with the exception of refined copper where it is now generally stipulated that not less than 99.50 per cent. of pure copper by wet assay shall be present) is deduced from the results obtained by the Cornish process of dry assay; yet it is well known that almost every sample submitted to the dry assayers is examined by the wet assay, either by operators employed by the works buying or selling copper material, or by practising analysts on their behalf, and that the results so obtained have a distinct influence on the results or "settled produces" returned by the dry assayers.

The writer proposes to detail and criticise shortly: The processes used in the estimation of moisture, the estimation of copper by wet assay, the dry assay of copper, to compare the results obtained by the two processes, with suggestions for an improved method of assay, and also to consider the methods used for fixing the price to be paid for copper in pyrites, copper ores, etc.

THE ESTIMATION OF MOISTURE.

This, although apparently a simple process, is conducted very differently by various operators. In copper assay offices the samples are generally dried on sheets of paper placed on the iron plates surrounding the furnaces, and, in consequence, the temperature at which samples are dried varies considerably during the day; in the morning soon after the fires are lighted the temperature of the plates is low, while, after the fires have been in use some hours, the plates are hot enough to char paper easily, and, although this difference may not materially affect the percentage of copper in low produce ores, etc., it becomes more important when rich precipitates, containing 80 to 90 per cent. copper, are being examined.

PERCENTAGE OF MOISTURE LOST AT VARYING TEMPERATURES. AIR BATH.

Burnt ore . . .	1.50 . . .	1.53 . . .	1.60 . . .
"5585 . . .	1.00 . . .
Precipitate465152 . . .
"7691 . . .	1.07 . . .

The writer was present some time ago at a sampling of copper ore, and rich English precipitates, when the sampling was admirably conducted, but the moisture was determined in the following most objectionable manner.

1lb. avoirdupois was weighed, and placed in a thin shallow circular pan about ten inches diameter, made of sheet copper, this was placed on a slow fire and gradually heated to dull redness, the sample being stirred occasionally, when the whole sample had been exposed to a dull red heat for about ten minutes, the pan was removed from the fire, and after cooling, the residue was removed and re-weighed, the loss being calculated as "moisture."

In treating chemically-made precipitate in this way, no doubt all the moisture was expelled, but much of the copper was converted into black oxide, while it is very probable that with pyrites and arsenical ores, sulphur and arsenic would be partially expelled, and the apparent percentage of moisture increased.

In some cases the determination is made by holding the drying-pan at a distance over an open fire, but in the writer's opinion it is desirable that the temperature and manner in which the moisture is to be taken should be more clearly defined than it is at present, for it is evident that in cases where the determination is made at the time of sampling, and the wet sealed samples are afterwards dried by the assayers, any

difference in the temperatures at which samples are dried will cause an apparent loss or gain in the amount of copper present in the parcel, resulting in pecuniary loss to either buyer or seller.

PROCESSES FOR THE WET ASSAY OF COPPER.

Although many processes for the estimation of copper are known, comparatively few have come into general use either by analysts in practice, or works chemists. Most of the latter use the well-known cyanide process; in some cases copper is precipitated as sulphide, and, after roasting in a muffle, is weighed as oxide; in a large copper works in South Wales, copper is precipitated with metallic iron, the spongy metal being converted into oxide by roasting in a muffle, and weighed as such. One or two analysts in this country use the iodide process (especially for the examination of refined copper), while occasionally the electro-deposition method, which is employed largely in the United States, is also used. I am informed that titration of ammoniacal copper solutions with standard solution of sulphide of sodium is the method occasionally employed by one analyst, while I am not aware that the processes, by precipitation as oxide with caustic alkali, ignition of cuprous sulphide mixed with sulphur in a current of hydrogen gas, or the precipitation by sulphocyanide of potassium and subsequent weighing as Cu_2S , are used by any analyst in the examination of samples for commercial purposes. The processes I personally employ in the examination of all copper ores and products are E. O. Brown's iodide process, and the electro-deposition method.

That more care is needed in the examination of copper products, will be evident, from the following results, which were obtained in two laboratories (not those of practising analysts) constantly engaged in this special work:—

Laboratory A.	Laboratory B.
3.25 . . .	3.00 . . .
3.25 . . .	3.10 . . .
3.38 . . .	3.29 . . .
3.49 . . .	3.26 . . .
3.35 . . .	3.28 . . .
3.71 . . .	3.49 . . .
3.51 . . .	3.60 . . .
3.20 . . .	3.10 . . .
3.17 . . .	3.07 . . .
3.27 . . .	3.20 . . .
3.21 . . .	3.24 . . .
3.40 . . .	3.23 . . .
3.02 . . .	2.90 . . .

and the following—

A.	B.
3.38 . . .	3.09 . . .
3.41 . . .	3.39 . . .
3.35 . . .	3.27 . . .
3.12 . . .	3.10 . . .
3.17 . . .	3.00 . . .

In each of these samples representing parcels of ore weighing from 200 to 350 tons a difference of one-eighth of 1 per cent. .125 per cent., in the percentage of copper, would cause the price to vary by 1s. 6d. per ton; or, taking the low average weight of 240 tons per parcel, a difference of £18 per parcel for every .125 per cent. difference in the copper assays.

Again, the following assays of burnt ores from copper extracting works show very serious differences.

CUPREOUS PYRITES.

<i>Works Assays.</i>	<i>J. W. W.</i>
8.02	8.70
8.88	9.14

Portions of the finely-powdered samples which had been tested by the works' chemist, were forwarded to me, and being examined by the iodide process gave the following results:—

8.82
9.01 per cent. Copper.

To the two following parcels I append the difference in value between the works' chemists and my own assays—

<i>Works Assay.</i>	<i>J. W. W.</i>	<i>Difference in Value of Parcel.</i>
7.86	8.42	£75 17s. 6d.
7.96	8.34	57 10s. 0d.

My results in the above list were obtained by the iodide process; the others, with the exception of the precipitate assays, by the cyanide process, the discrepancies being due, in my opinion, chiefly to careless work by the operators, but partly also by the difficulties inherent to the method employed. Thus, to obtain accurate results, it is well known that the solution must not contain silver, zinc, nickel, cobalt, or manganese, and that the proportions of free ammonia and ammoniacal salts must be the same as in the copper solution used for standardising. The cyanide of potassium solution also decreases in strength on keeping, and has to be frequently titrated with known amounts of copper.

The direct titration of solutions of copper ores, mattes, precipitates, &c., obtained by dissolving in acid, and adding excess of ammonia, is not now, I think, used by any analyst; but to my certain knowledge it was the process used five years ago in an assay office where large numbers of copper samples are regularly examined. The results obtained by it

were used to check the Cornish dry assays, and its accuracy was assumed from the fact that it is described by a well-known recent writer on metallurgy.

The modified cyanide process now used in copper extraction and alkali works is as follows, for poor cuprous pyrites, etc.:—

The finely-powdered ore, 100 grains (in some works a smaller amount is taken) is dissolved in nitric and hydrochloric acids, filtered from siliceous matter, and largely diluted with water. Sulphuretted hydrogen gas is now passed through the solution, and the precipitated CuS , PbS , Bi_2S_3 , As_2S_5 , etc., are collected on a filter, washed, dried, and roasted in a muffle. The roasted product is dissolved in nitric acid, the solution evaporated to dryness with excess of pure sulphuric acid, heated till sulphuric acid fumes are evolved, and allowed to cool, diluted with water, excess of ammonia added, the solution filtered, and the blue filtrate titrated with solution of potassium cyanide, the standardising of which is made with pure copper-foil, conducted in precisely the same manner and under the same conditions (weight of copper, amount of sulphuric acid, volume of ammonia, bulk of solution, manner of addition of the cyanide solution) as in examining copper ores. This process, if carefully conducted, should give accurate results, but very often the reverse is the case. Thus, in examining a sample of cuprous pyrites, the following results were obtained by four operators in different works' laboratories:—

3.07 . 3.16 . 3.21 . 3.27

My own single assay by the iodide process was 3.34 per cent. This result was not challenged, nor was I requested to repeat the assay; the difference in value on this parcel between the highest and lowest assay—3.34, 3.07, .27—say $\frac{1}{4}$ per cent., would be £39, a matter of some importance.

In the following cases, the results of operators obtained in different laboratories and my own results are more in accord:—

<i>A.</i>	<i>B.</i>	<i>J. W. W.</i>
3.30	3.26	3.29
3.38	3.40	3.42
3.17	3.13	3.15
3.11	—	—
3.01	—	3.04
		3.03

The difficulties previously mentioned, alteration of strength of standard solution, necessity of having a similar amount of free ammonia and ammoniacal salts present, as in the copper solutions used for standardising, and the want of definition in the end reaction, in my opinion, make this process a very undesirable method of analysis; to the use of it, and the following process for the assay of copper precipitates, I attribute much of the annoyance, and occasionally pecuniary loss, caused by discrepancies in the results of different operators.

The following method is much used in copper extraction works for the estimation of copper in precipitates, and other products rich in copper:—20 grains of the dried precipitate is dissolved in pure nitric acid, and the solution is evaporated to dryness with excess of sulphuric acid. The residue is heated till sulphuric acid fumes are evolved; after cooling the mass is dissolved in water, filtered from the insoluble residue, and the filtrate precipitated by a current of SH_2 gas, the CuS collected on a filter, washed, dried, and the precipitate removed from the filter which is burnt. The precipitate with some pure sulphur is now added to the filter ash in a porcelain crucible, and ignited in a muffle till the weight remains constant. It is then dissolved in nitric acid, diluted, and excess of ammonia added; the

small precipitate formed is washed, dried, ignited, and its weight subtracted from the original weight of the calcined oxide which is then calculated to the percentage of metallic copper. My experience of this process is that it gives variable and high results, the following figures being obtained by an analyst who employs this method, and myself by the iodide process, on portions of the same finely divided sample. My results have since been confirmed by trials with the electro deposition method :—

Precipitation etc.

The precipitation of copper as sulphide by SH_2 , followed by ignition of the dried sulphide mixed with sulphur in a current of hydrogen gas is recommended by Fresenius, *Journ. Chem. Soc.*, Abstracts, 1877, vol. ii. p. 650; and also by Burre, *Journ. Chem. Soc.* 1878, vol. ii. p. 337, for the estimation of copper in nickel and bronze coinage. In the latter paper it is shown that the current of hydrogen cannot be replaced by carbonic anhydride, as the results are then rather high. It is also stated that the results obtained by heating a mixture of sulphur and sulphide of copper in a covered crucible, removing the lid for a few seconds at intervals till the excess of sulphur has been volatilised, and weighing the resulting mixture of Cu_2S and CuO (containing theoretically 79.87 per cent. of metallic copper) gives no certain indication of the metallic copper present. My experience confirms this statement, and is the result of many hundreds of ignitions of mixtures of Cu_2S and sulphur, obtained by precipitating sulphuric acid solutions of copper with hyposulphite of soda; and the addition of carbonate of ammonia as recommended by the late David Forbes gives no better results. In my experiments, the ignitions were made over a good Bunsen burner, and my object in weighing the products was to get a rough idea of the percentage of copper present in the sample under trial. An objection to this process is made by A. G. Haddock (*Pharmaceutical Journal*, iii. 10, p. 801), who states that the mixture of Cu_2S and sulphur is very apt to boil over on heating, unless great care is taken in regulating the heat. I have, however, made several hundreds of these ignitions without experiencing the slightest difficulty. I am not aware that any English analyst uses either of these processes for the determination of copper in ores; and the fact that any bismuth present would be weighed with the sulphide of copper* is an objection to its use.

The method by precipitation as oxide by caustic potash or soda, after separating the copper from other metals, is recommended by A. G. Haddock, in the *Pharm. Journ.* previously quoted, as especially suitable for the determination of copper in cupreous pyrites and other ores, etc., containing but little of the metal.

The titration of ammoniacal copper solutions by standard solution of sulphide of sodium is, I believe, used by one analyst in this country; but the fact that

the sulphide solution rapidly decreases in strength, and requires standardising every time it is used, renders the process disadvantageous.

The methods of separating copper by precipitation with sulphocyanide of potassium or ammonium, and as metal by metallic zinc, are not, I believe, used by any analyst in the examination of commercial samples.

The following process is used at a large copper smelting works in South Wales.

The ore, matte, precipitate, etc., is dissolved in nitric acid, excess of sulphuric acid is added, and the solution evaporated till sulphuric acid fumes are evolved; after cooling, the residue is treated with water, and filtered. To the clear solution strong solution of sulphide of sodium is added in excess, but care is taken that the mixture has a distinct acid reaction. The precipitated sulphides are filtered off and washed, then treated with an alkaline solution of sodium sulphide to remove arsenic or antimony. The precipitate of CuS is now dissolved in nitric acid, sulphuric acid added, and the solution evaporated to expel the nitric acid, cooled, treated with water, and filtered. From the solution copper is precipitated by metallic iron, the precipitated metal washed, dried in a platinum crucible, and converted into oxide by roasting in a muffle; after weighing, it is dissolved in nitric acid, and excess of ammonia added; the small precipitate of oxide of iron formed is washed, dried, and ignited, its weight being deducted from the oxide of copper. I have not tried this process myself, but am informed that it gives satisfactory results when tested with a known weight of pure copper. The following results were obtained in examining a sample of copper matte by the above process at a copperworks, and by myself :—

Works chemist by iron precipitation method	66.92
Iodide process, J. W. W.	66.78

By the addition of solution of sodium hyposulphite to hot sulphuric acid solutions of copper, a flocculent precipitate of subsulphide of copper mixed with sulphur is obtained, which can be readily filtered and washed with boiling water; arsenic and antimony if present, are also precipitated; tin, iron, zinc, nickel, cobalt, and manganese are not precipitated. On igniting the precipitate the excess of sulphur, and most of the arsenic (if any is present) is expelled, an impure subsulphide of copper remaining. I have used this method extensively for separating copper from solutions of ores, mattes, precipitates, etc.; it dispenses with the use of sulphuretted hydrogen, which is in some localities an objectionable reagent.

The process described by E. O. Brown (*Quarterly Journal of the Chemical Society*, vol. x. p. 65, and which is also described in Dr. Percy's "Metallurgy of Copper") is based on the fact that when solutions of cupric salts are mixed with excess of iodide of potassium, subiodide of copper and free iodine are formed; and that this iodine can be titrated with a solution of hyposulphite of soda.

1000 grains of recrystallised hyposulphite of soda are dissolved in a Winchester of distilled water, and the solution is standardised by dissolving portions of electrotype copper, varying in weight from 6 to 8 grains, in nitric acid, boiling to expel nitrous fumes, and diluting with water. Solution of sodium carbonate is now added till a permanent precipitate forms, showing that all the free acid has been neutralised; and then acetic acid in excess. To this solution iodide of potassium in excess is added, and the flask or beaker shaken till it is dissolved. The solution of hyposulphite is now run in gradually from a burette, when most of the free iodine is removed, starch solution is added, and the titration

* Since writing the above, I have been informed that the method by igniting subsulphide of copper in a current of hydrogen gas is used in one copper extraction works, and in testing a sample of cupreous pyrites containing from 3 to 4 per cent. of copper by net assay, the results by this process, and my own by the iodide process, differed by .02 per cent. only.

finished in the usual manner. From the number of measures of hyposulphite solution used, the value of 1000 measures can be calculated.

In the original paper experiments are recorded, showing that dilution of the solution within wide limits had no effect on the reaction, and it is stated that no metals except lead and iron interfere—the former owing to yellow iodide of lead being formed, preventing the end reaction from being sharp, the red colour of ferric acetate also interferes, and I am also inclined to think that the ferric acetate liberates iodine from potassium iodide. No experiments are, however, recorded regarding the action of other metals, and it may be stated that in this and other papers generally on the estimation of copper, experiments made on weighed quantities of pure copper alone are given in proof of the accuracy of processes; and although this may be satisfactory for assays of refined coppers or chemical products, it is not so when minerals containing—besides copper—varying amounts of silver, arsenic, antimony, lead, bismuth, zinc, nickel, cobalt, manganese, iron, etc., have to be examined.

The writer has examined many hundreds of samples of all descriptions of copper ores and products by this process, and would recommend it as a most valuable method, far superior to processes previously described in this paper; and for copper ores and products (as distinguished from solutions of pure copper salts), it is, in his opinion, preferable even to the electro-deposition process.

For cupreous pyrites, burnt ores, etc., the following methods may be used: 50–100–150 grains are dissolved in acids, evaporated to dryness with excess of sulphuric acid, diluted with water and filtered. From this solution the copper is separated with hyposulphite of soda at Cu_2S , the precipitate dried, ignited, dissolved in nitric acid, evaporated with sulphuric acid to separate traces of lead, diluted with water and filtered, sodium carbonate added in excess, and then acetic acid to acid reaction. Potassium iodide is now added, and the titration conducted as in standardising.

As an alternative method the ore may be calcined, dissolved in hydrochloric acid, the ferric salt reduced by boiling with solution of sodium sulphite, and then passing SH_2 gas through the cold solution. The precipitated sulphides are washed, dissolved in nitric acid, and the process conducted as before.

Richer copper ores, mattes, precipitates, etc., are dissolved in appropriate solvents, the weight taken, and is generally such that from 7 to 9 grains of metallic copper is present. The solutions are precipitated either with hyposulphite of soda or sulphuretted hydrogen gas, the sulphides being dissolved in acids, and treated as before.

To satisfy myself regarding the accuracy of this process, I made many experiments, using known weights of pure electrolytic copper, silver, arsenic, antimony, lead, cadmium, bismuth, tin, manganese, zinc, and iron salts. The solutions were made to represent cupreous burnt ores, mattes, cupriferrous lead regulus, second quality, and rich precipitates, etc. Experiments were also made in many cases with the metals separately.

dissolved in nitric acid, evaporated to dryness with sulphuric acid, filtered, etc., excess of sodium carbonate and acetic acid added, and the titration made as usual.

In the experiments of mixtures representing burnt ores, precipitates, etc., the solutions of the metals were mixed, evaporated to dryness with sulphuric acid, diluted with water, filtered, the hot solution precipitated with hyposulphite of soda, the precipitate washed, dried, ignited and weighed. The impure Cu_2S was dissolved in nitric acid and treated as previously described.

Some time ago, experiments were made by the writer to see if the prejudicial action of ferric salts could not be eliminated, so that the process could be used to examine copper precipitates containing from 60 to 90 per cent. of metallic copper without previously separating the iron. For this purpose solutions of arsenic acid and phosphate of soda were added to the copper solutions previous to the addition of sodium carbonate and acetic acid, arseniate and phosphate of iron were precipitated, and the iodine reaction was not affected. When phosphate of soda solution was added to copper solutions, no change occurred in the amount found on titration, or when small amounts of iron were present; with more iron the large amount of precipitated phosphate or arseniate of iron seemed to interfere, representing in a 60–70 per cent. precipitate, about 40 per cent. in the amount of copper present.

8'759 Cu taken 1'95 Fe 15grs. crys. Phosphate of Soda	8'729 Cu found

An objection to this process has been made by certain copper extraction works; and supported by a well-known metallurgical chemist. It is stated that arsenic present as arsenic acid in solutions of copper separated in the ordinary course of analysis from cupreous pyrites, in an acetic acid solution liberates iodine from solution of potassium iodide, and that this iodine measured in the usual way by standard hyposulphite, caused the copper assays to be above the true percentage. This objection was strenuously urged some three years ago by buyers of cupreous pyrites, and letters detailing experiments made in refutation were written by me, and were copied and forwarded by my then employers to the buyers concerned.

In the following experiments, portions of electrotype copper and metallic arsenic were dissolved in nitric acid, the solutions boiled well and evaporated to a small bulk, diluted, an excess of sodium carbonate solution and acetic acid added, and the titrations made as usual.

2'021grs. Copper taken 2'00 Metallic Arsenic	2'019 Cu found
4'121grs. Copper taken 4'018 Metallic Arsenic	4'109 Cu found
2'065grs. Copper taken 20'2 grs. Arseniate of Soda	2'066 Cu found

21'1grs. of arseniate of soda were treated with strong nitric acid, the excess being removed by evaporation; sodium carbonate being then added in excess and the solution acidified with acetic acid, and 30grs. crystals potassium iodide added. After standing 25 minutes, traces only of iodine were liberated.

2grs. metallic arsenic were dissolved in excess of nitric acid, and evaporated to a small bulk, then sodium carbonate added in excess, and the solution acidified with acetic acid, 30grs. crystals of potassium iodide were added, after standing 25 minutes, traces only of iodine were liberated.

30grs. of potassium iodide, water and acetic acid were mixed, traces only of iodine were liberated after standing one hour.

I regret that more recently this objection (the interference of arsenic) was apparently confirmed by the following "doubtful" assays which were supplied to copper extraction works. It is usual for works buying cupreous pyrites to send their wet assays of parcels to the dry copper assayers who "settle" the produce, and it is understood that there must be a certain margin between the wet assay and the "settled produce," for example in pyrites containing 3'00 per cent. of copper by accurate wet assay, the settled produce will be about 2 $\frac{1}{8}$ per cent., no buyer would care to give 2 $\frac{1}{8}$, but formerly it might have been settled at 2 per cent., or even lower. In these samples some difficulty occurred, the copper assayer was requested to send his wet assays and afterwards portions of the samples his chemist had operated on to be tested at the buyers' works. The results obtained confirmed their original wet assays, and a letter was received stating that the results showed most clearly that the objection previously taken to the iodide process was a valid one, and that it was seriously inaccurate for testing samples of cupreous pyrites.

The assays were as follow:—

Two Parcels.	A.	B.
Original works wet assays	3'26	3'12
Portions of samples assumed to have been operated on by iodine process by copper assayers' chemist; tests made at copper extraction works	3'25	3'08
"Doubtful" results assumed to have been made by iodide process and sent to the copper extraction works	3'38	3'31

I have examined my note-books carefully, and cannot find any record of the examination of these samples. All parcels I examined are numbered consecutively, and there are none missing; moreover I was not informed that such a serious blunder had occurred. I am therefore compelled, however much I may regret doing so, to assert that the results 3.38 and 3.34 per cent. are "doubtful" assays, and are not of the slightest value in determining the reliability or otherwise of the iodide process.

The method described as De Haen's process in "Fresenius' Quantitative Analysis," 6th edition, p. 230, is a modification,—to a neutral solution of copper, or a solution moderately acidified with sulphuric acid, potassium iodide is added, and the liberated iodine titrated as usual. Bayley, in a paper on the analysis of copper, zinc, and nickel alloys (*Philosophical Magazine*, (5) 6, p. 14; and *Journal of the Chemical Society*, 1879 (2), p. 485), uses the same process, dissolving the alloy in nitric acid, then expelling it by evaporation to dryness with sulphuric acid; after cooling, the sulphates are dissolved in water, potassium iodide added, and the liberated iodine titrated as usual. An objection to this modified process is that iodine is more readily liberated from solutions of iodide of potassium mixed with sulphuric acid than with acetic acid, and there can also be no doubt that if arsenic acid is present, iodine will be liberated and calculated as copper. To the neglect of this fact, and disregarding that all my titrations were made in acetic acid solutions, I attribute the doubts expressed by some chemists as to the accuracy of E. O. Brown's process.

The method by precipitation with metallic iron, and weighing the spongy precipitate of metallic copper, although used to some extent abroad, is not, I believe, used as a commercial method in this country.

The deposition of copper by the voltaic current has not become a standard method in this country, though it has been used by some operators, but it is largely used in the United States. The statements made by various writers with regard to its accuracy are very discordant.

Thus in a review of the pocket book for manufacturers of soda, potash, and ammonia (*Chemical News*, vol. 47, p. 140), it is stated on the authority of G. Lunge, "that the electrolytic method for the determination of copper in cupreous pyrites has not yet been adopted in copperworks, as it has not been found practicable to obtain the copper sufficiently pure by a single precipitation." He recommends the precipitation of copper as sulphide, with certain precautions; and the ignition of the precipitate mixed with sulphur in a current of hydrogen or coal gas.

A. G. Haddock, in his paper previously quoted, in speaking of the deposition of copper from sulphuric acid solutions by electrolysis, recommends the addition of a little nitric acid to the solution, and precipitation in a platinum dish. He states that much difficulty is experienced in precipitating the last traces of copper, and recommends that these traces should be precipitated with sulphuretted hydrogen, and weighed as Cu_2S , the amount of metallic copper so obtained being added to that directly obtained by electrolysis. He advocates its use as one of the few reliable methods for the separation of copper and zinc, and states that two small Bunsen elements give sufficient current. Contrary to the experience of Luckow, who has also described a modification of this process (see "Crooke's Select Methods of Chemical Analysis, or Quantitative Analysis," T. E. Thorpe, p. 209), he states that arsenic interferes, depositing on the copper towards the end of the deposition.

In the *Chemical News*, vol. xlv, p. 279, a paper is published by J. B. Mackintosh, which had been read

before the American Institute of Mining Engineers, May, 1881, on the "Electro-deposition of Copper." He describes Luckow's method, and gives results by it, and also by electrolysing sulphuric acid solutions of pig copper and brass, showing that the electro-deposition method from solutions containing organic acids gave too high results. In the discussion following the reading of the paper, Mr. S. P. Sharples, of Boston, U.S., referred to some experiments made by himself, and also to those of Mr. E. V. McCauldless, made in 1864, and published in the *American Journal of Science and Art*, January, 1865, on the "Electro-deposition of Copper from a Sulphuric Acid Solution in a Platinum Dish." These experiments are of the same character as are generally published; pure electrolytic copper was dissolved in nitric acid, the solution evaporated to dryness with sulphuric acid, the residue dissolved in water and electrolysed. Almost any process will give good results with such a solution, but it is a very different matter when arsenic, antimony, bismuth, silver, or large amounts of ferric salts are present.

Mr. Sharples stated that a large excess of free acid, if present, must be neutralised with ammonia, but that a small amount of nitric acid is not prejudicial. He takes from two to five grammes of ore, etc., dissolves in nitric and sulphuric acids, heats to boiling, dilutes with water, and filters into a platinum dish, electrolysing the solution with the current from two Grove's cells, stating that if the dish is put in the circuit in the evening, the copper is generally completely precipitated the next morning. He remarks that the commercial allowance for errors is half of one per cent., but that duplicate assays rarely vary more than one-tenth of one (10) per cent.

My experience with this process, using the current from two large Daniell's cells, and precipitating the copper in a platinum dish, is that the process is not satisfactory in all cases; the results are accurate with pure solutions of copper acidified with sulphuric acid, but if silver or bismuth is present, they are deposited; and in one experiment tin was also deposited with the copper. In the presence of ferric sulphate the precipitation is delayed, while in a nitric acid solution rendered ammoniacal and acidified with sulphuric acid, a sensible amount of copper was left in solution. With refined or bar coppers and rich precipitates, eight or nine grains of copper may easily be precipitated during the night. Mattes, ores, cupreous pyrites, and burnt ores are rarely precipitated in one night, often requiring forty-eight, and sometimes seventy-two hours for complete precipitation, even after a double evaporation with sulphuric acid, to expel the nitric acid as completely as possible.

In the following experiments the deposited copper was well washed with water, the dish was then rinsed with alcohol, and dried in the air-bath at 212–220° F.

In all the above experiments the solutions of the metals or salts in nitric acid were mixed and evaporated to dryness with sulphuric acid, the residue dissolved in water, the solution filtered and electrolysed. In working this method of analysis recently, I have experienced difficulty in precipitating the last traces of copper, having had to leave the dish in the circuit for forty hours.

Bar Copper—results by iodide process—

Deduct silver	95·25	95·31
	16	16
	<hr/>	<hr/>
	95·09	95·15 per cent.

My experience is, that while the results with refined or bar coppers and rich precipitates agree well with those obtained by the iodide process, those obtained by electrolysing sulphuric acid solutions of mattes, copper ores, etc., are generally slightly below the true percentage.

With burnt ores, cupreous pyrites, and ores containing but little copper, I first precipitate with sulphuretted hydrogen, dissolving the sulphide in nitric acid, and evaporating this solution with excess of sulphuric acid, the sulphates dissolved in water give a solution from which copper (and bismuth) is readily deposited. The results by the battery process are generally from '01 to '04 per cent. higher than by the iodide process, this being caused by a slight deposit of bismuth.

In the following case, where much bismuth was present, the result by the battery process is considerably higher :—

Battery or electro-deposition process	5.39 per cent.
Iodide process, J. W. W.	5.09

In all cases where mattes were examined, and with some copper ores, it was necessary to leave the dish in the circuit for two nights, in order to ensure complete precipitation.

Recently, I have been in correspondence with American analysts regarding this process, samples having been examined by the iodide process by me, and by their electro-deposition process, the results show that in three of the four samples examined their results were rather higher than mine. The results on the copper matte, however, are very concordant :--

AMERICAN COPPER ORES CONTAINING ARSENIC,
ETC.

Electro-deposition, J. W. W.	63.20	—	—

Large quantities of copper mattes and ores are bought in New York on results obtained by the electro-deposition method, and these parcels are sent

over here to be smelted and refined. Arriving in Liverpool, the ores and mattes are resampled, and assays are made by the Cornish assayers; serious discrepancies have occurred, causing much annoyance and loss to the importers and their agents in New York. In two cases it was said that the Cornish settled produces were thirteen and five per cent. respectively below the American assays, this was due in some measure to defective sampling, either here or in New York; but it was also admitted that the settled produces were lower than they should have been. My wet assays and the "settled produces" dry assays were as follows:—

<i>Wet Assays</i>		<i>Settled Produce</i>		
<i>Iodide Process.</i>		<i>Dry Assays.</i>		<i>Margin.</i>
<i>J. W. W.</i>				
48.09 48.16	48.12	45½		2.62
47.87 47.85	47.86	44½		3.24

Two per cent. on this material would be a fair margin between the wet and dry assays, and the loss to the vendors of these two parcels would be £11 5s. and £18 15s. for five-eighths per cent. and one and a quarter per cent. respectively.

THE CORNISH PROCESS OF "DRY ASSAY."

A detailed description of this process, which is not used for the valuation of copper ores and products in any other country but England, may be found in Dr. Percy's Metallurgy, volume, "Copper, Zinc, Brass," and also in Phillips' "Elements of Metallurgy." Its advocates claim that the percentage of copper obtained by it represents the amount which will be produced in the smelting operation, and that the assay button of fine copper will give a fair indication of the quality of the metal which will be obtained in smelting. How far the latter statement is correct will be shown presently.

Briefly, the process consists in separating the copper from the earthy constituents of the ore by a series of fusions in an air furnace—first into a matte or regulus containing, besides copper and sulphur, a certain amount of iron, and small quantities of other metals, then converting this regulus into a mixture of oxides of iron and copper by calcination; afterwards reducing the copper and a portion of the iron to the metallic state as "coarse copper," by fusion with tartar, borax, nitre, carbonate of soda, and salt, refining this coarse copper by oxidation, when in the molten state; the latter part of the refining process being conducted under a mixture of "refinery flux" and salt, a button of "refined copper" and refinery slag resulting, then running down the refinery and coarse copper slags with tartar, in order to obtain the last portions of copper in a prill, which is generally assumed to be half copper.

The first process or "fusion for regulus," is conducted differently by various operators. Thus, some assayers in operating on poor cupreous pyrites and burnt ores, run a "coarse regulus" (i.e., a regulus containing an excess of iron); this is afterwards "warmed" or slightly roasted, and again melted with fluxes to obtain a "good regulus." This method of procedure is said to give a higher result than if the sample is run down for a good regulus in the first instance. Arsenic, if present in any quantity, is always expelled by roasting before the sample is fused for regulus, and if necessary sulphur is added to replace that lost during the roasting.

The regulus is powdered and then calcined to expel the sulphur, a mixture of oxides of copper and iron remaining. If the calcination has been effected in a crucible, tartar, nitre, borax (sometimes a little sodium

carbonate) are added, and mixed with the oxides; salt is added to cover the mixture, the crucible placed in an air furnace, and fused for coarse copper. After pouring the melted contents of the crucible into an assay mould, it is replaced in the furnace, the button of coarse copper added, together with some refinery flux and salt, the metal being submitted to a preliminary refining or "washing." The "washed copper" is then refined, by oxidation, in the molten state, "refinery flux" being added when the operation is nearly completed. The refined copper is poured into an assay mould, the slag separated from it, and fused together with the slags from the coarse copper fusion and "washing," with a little tartar to obtain a "prill" of impure copper; this is generally assumed to be half copper, though in some cases, where it is heavy, as from rich precipitates and bar coppers, it is refined and weighed with the button of "fine" copper.

The standard weight of ore operated on is 400 grains, but for mattes, rich precipitates, bar coppers and copper material generally containing over 50%, 200 grains, or as it is generally termed, "half trial," is operated on.

Copper mattes are calcined direct, fused for coarse copper, washed and refined. Rich precipitates are fused for coarse copper, washed and refined, while bar coppers require washing and refining, or very pure samples refining only.

It is well known that the Cornish dry assay gives results always below the truth; in fact, contracts are made based on the assumption that with certain classes of material, cupreous pyrites, burnt ores, mattes, precipitates, etc., there will be a definite margin between the results of wet and dry assays; and when this margin from any cause is greater or less than usual, much dissatisfaction occurs, and sometimes serious pecuniary loss results. But it is not generally known that in many cases the produces obtained are very variable and almost unreliable. Thus, to obtain concordant results, it is absolutely necessary that the same weight of material should be operated on in exactly the same manner; and if any changes are made, the results will not be in accord. Even in operating on the same weight of material, many cases are known to me where 1% difference occurred in two assays of the same sample (70–90% produce), and in assays of copper mattes ½ to 1% discrepancies in assays by the same operator are of frequent occurrence. It would be impossible to obtain concordant results if different weights of ore, which can be safely used in wet assays, were employed. Thus, I have given results of wet assays where 50, 60, 100, 150 grains of ore were operated on by different processes, and the results were concordant; but if these "proportions" (not weight in grains) were employed in making four dry assays, I am afraid the results would be anything but satisfactory; and it is well known that when "half trial" and "whole trial" assays are made on the same sample, the results of the latter are always higher than the former.

Again, in the "fusion for coarse copper," the object of the assayer is to get *all* the copper, together with a little iron and small quantities of other metals, in the "coarse copper," for if it is brought down "too coarse," a greater loss occurs in refining. This fact was brought prominently before me by the following assays of a sample of copper precipitate:—

Wet assay iodide process, J.W.W.	87.7% Cu
Dry assays with refined prill	85½
Margin	2½

* Refinery flux.—A mixture of nitre, tartar, and some salt, which has been deflagrated in an iron pot, with a red-hot iron bar. The proportions are so adjusted that a slight excess of nitre remains which exerts an oxidising or refining action on the molten copper.

The margin between the two processes being higher than usual, on investigation it transpired that the copper in the first fusion was "too coarse," hence the loss; on a re-assay, 86% was easily obtained, the sample being settled at 85½.

Wet assay	87½
Dry re-assay	86
Settled produce	85½

Again, the process sometimes fails in the hands of men who have been making dry assays for years. Thus, a parcel of burnt ore (many samples of which were being tested at intervals) was assayed on behalf of the vendor, giving a produce of 2%, it was suspected that a higher percentage was really present, my wet assays on two separate samples being 3·10–3·12%; the buyers' assayer agreed to settle this parcel at 2½%, a fair produce, as ½% is the usual margin with this percentage of copper. A difference of ½% on this parcel—and it must be remembered that the vendor's assay was the lowest—would amount to £36 in money value.

Wet assay, burnt ore, J.W.W.	3·10–3·12%
Vendors' assayers' produce	2
Settled produce with buyers' assayer	2½
½ money value on parcel	£36

The following is a much more serious case of error, in which four of the most experienced copper assayers were concerned. Several parcels of copper material being sold, samples were sent to the copper assayers to be examined in the usual manner; the assayers could not agree on a produce, and the samples were referred to a third assayer. A sample was also examined by the iodide process of wet assay, by me. The results were as follow:—

Vendors' assayer referred on.	33½
(but asked 31% at first)	
Buyers' assayer, highest produce	32½
Referee's assays	33
Wet assay, iodide process, two separate samples J.W.W.	37·01

The results of the wet assay being much higher than those of the dry assays, further trials were made by the referee, by a modified process, when 35½ per cent. was obtained. The return made by the referee was 34½ per cent.

Referee's re-assays by modified process	35½
Referee's return as umpire to vendors' and buyers' assayers	34½

When the buyers' assayer received this produce he forwarded his own and the vendors' assayers' results, asking also if an error had not occurred; he stated, also, that another assayer, a well-known man with large experience, had given similar material, when acting as umpire, in favour of the buyer. On receiving the above return, the buyers, who are copper smelters, informed their assayer that the produce, 34½ per cent., was higher than their wet assay. The dry assays were made by four of the most experienced copper assayers, all well-known men; and the smelter's chemist should be able to make an accurate wet assay; but in my opinion the results are disgraceful to all the parties concerned. The parcel was only a small one, and as the assayers all obtained approximately the same produce in the first instance, it is evident that the samples were alike; while a modified process of assay, giving results 2½ per cent. higher, shows that the assayers did not know how to treat the sample, although they had been examining parcels of similar material for years. When the money value of the parcel is calculated from the results of the various assayers, the importance of the matter is still more evident. For obvious reasons I cannot record tonnage

and price per unit; but I have verified the latter by referring to the *Mining Journal*.

Value deduced from vendors' assay, 33½	£	s.	d.
Mean	618	8	6
Buyers' assay, 32½	611	1	9
Referee's first assays, 33	633	15	0
Referee's modified process; produce actually obtained, 35½	694	13	9
Referee's return, 34½	677	12	6
Difference in value between assays by buyers' assayer and referee's modified process	60	18	9
Difference in value between mean value by buyers' and sellers' assays and referee's return as umpire	36	10	9

The following results of assays of copper matte also reveal serious discrepancies. Several hundred tons of copper matte were imported, 470 tons were assayed and settled at 46½. Two parcels, each representing 100 tons matte, were assayed by other assayers, and settled at 48 per cent.

470 tons settled at	46½
200	48
Wet assays of the 200 tons gave by the iodide process, J.W.W.	49·29
	49·33

In the last two samples, representing 200 tons of matte, strong pressure had evidently been applied to the buying assayer; the margin is much lower than usual, and the buyers suffered. The results also show that serious errors often exist between assays made by different operators. If 48 per cent. was a fair produce for the parcel, a difference of 1½ per cent. on the 470 tons settled at 46½, at 10s. per unit, would amount to £293 15s.; while if 46½ per cent. was correct, the loss to the buyers on 200 tons, settled at 48 per cent., would amount to £125.

The extreme variation in the results of dry assays is also shown in the following assays; the referee and vendors' assayer were the same, but different men, both recognised copper assayers, acted for the buyers.

Vendors' Assayer's Results.	Buyers' Assayer's Results.	Referee's Return.
57½	57½	57
57½	56½	57
58	57	57
59½	58½	61½
59	58½	60½

Again, the presence of lead has a great influence on the results of copper assays by the Cornish method. If not present in too large a quantity, it seems to prevent loss of copper during the "refining," and gives a higher produce. Some time ago a precipitate, containing about 4 per cent. lead, and 70–85 per cent. of copper, was largely produced, and samples were sometimes settled with less than 1 per cent. margin between the wet and dry assays. Lead is not easily expelled in refining, and two buttons of "fine copper," said to be quite "fine" by experienced assayers, and which would be "burnt" if the refining was carried further, contained the following percentages of lead:—

FINE COPPER ASSAY BUTTONS, CORNISH DRY ASSAYS.

(a.) Metallic lead	2·21%
(b.) Metallic lead	1·78

I regret that my research in this direction came to an abrupt termination. I was unable to obtain more material for experiments.

The effect of lead on the results of dry copper assays is also shown in the following sample of copper precipitate:—

Wet assays, iodide, and electro deposition process, on two samples	77·63–77·68%
Buyers' assayer's results, dry assays	76·0–76·9
Settled produce	74½
Metallic lead present	1·01

A very good illustration of the confidence and reliance to be placed on results obtained by dry assay.

The presence of some amount of lead, however, has a very different influence, as it is impossible to expel it without serious loss of copper. With copper ores containing much lead, it enters the regulus, which is fusible and difficult to calcine; it also enters the "coarse copper" and causes excessive loss in refining; in fact it is impossible to obtain concordant results. A sample of cupriferous lead regulus gave the following results:—

Wet assay iodide process, J. W. W.	11.63%
Vendors' assayer's dry assays	10½–11½
Buyers' assayer's highest dry assay	11½
Settled produce	12

12½ per cent. was asked for this parcel by the vendors' assayer, whilst the buyers' highest assay was 11½; but, taking the wet assay, 11.63 per cent., into consideration, it was agreed that 12 per cent. should be the settled produce, although neither of the assayers could make that percentage.

The assays of this parcel also show that buyers and sellers may state in their contracts for the purchase and sale of copper ores, etc., that the samples shall be assayed by Cornish assayers in the usual manner—i.e., by Cornish dry assay; yet it by no means follows that this will be carried out; in fact numerous cases are known to me where the wet assays have had more influence in deciding the "settled produce" of a parcel than the results of the dry assays.

The effect of a small percentage of lead on the assays of copper mattes, ores, etc., is shown in the following assays:—

COPPER MATTE.

Vendors' assayer's dry assays	46½, 45½%
Settled produce	45½
Wet assays, J. W. W., iodide process	48.55, 48.14
Margin between wet and dry assays	3.00

COPPER ORE CONTAINING LEAD.

Vendors' assayer's dry assays	6, 6½%
Settled produce	5½
Wet assays, J. W. W., iodide	7.99, 7.97
electro deposition	7.99
Margin between wet and dry assays	2.23

BURNT ORES.

Vendors' assayer's results, 9%, will settle at	8½%
Buyers' assayer's highest produce	8½
Referee's assay	8½
Wet assays, J. W. W., iodide	10.174
electro deposition	10.176
Margin	2.05

I have known many samples of burnt ore similar to this settled under 1½ per cent. margin between wet and dry assays.

BURNT ORE.

Vendors' assayer's results	2½, 2½%
Buyers' assayer would not settle at a higher produce than	2½
(Which was accepted.)	
Wet assays, J. W. W., iodide process	3.60
electro deposition	3.61
Margin between settled produce and wet assays	1.23

Burnt ores with this percentage of copper are rarely settled with more than 1 per cent. margin between the wet and dry assays. Assuming this parcel to have been settled at 2½ per cent. (1 per cent. margin between the wet and dry assays), the difference in money value would amount to £31, and if the parcel had been settled at 2½ per cent., £15 more would have been received by the vendors.

That 1½ per cent. is a high margin for this percentage burnt ore is evident, from the following assays, of richer parcels of the same ore

	(a)	(b)
Vendors' dry assays	4½, 4½	4½
Wet assays, iodide process, J. W. W.	5.66, 5.71	5.71
Margin between wet and dry assays	1.16, 1.085	1.085

The above results, as well as the following ones, in my opinion, support the views of some persons, that a change in the method of valuation of copper ores and products is desirable. Take, for instance, the following assays of

COPPER MATTE.

Vendors' assayer sent produce	70½%
assay weighed	70½
Buyers' assayer's results (four trials)	69½, 69½
Another assayer's result	69½
Settled produce	69½
Wet assays, J. W. W., iodide	71.86
electro deposition	71.83
Margin between wet assay and "settled produce"	2.09

Large quantities of cupreous pyrites are used in the manufacture of sulphuric acid, the copper being extracted from the burnt cinders. The copper contents of these pyrites and cinders are bought and sold by the produce obtained by dry assays, and the results are often very unsatisfactory. The assays of a parcel of pyrites were as follows:—

WORKS WET ASSAY, 3.10% COPPER.

Wet Assays.

Iodide Process.	J. W. W.
50 grains	3.157%
60 "	3.175
150 "	3.161

100 grains electro deposition (J. W. W.) 3.194
Results rather high owing to traces of bismuth.

The vendors' assayer would settle this parcel at 2½ per cent.; but the buyers preferred referring if it could not be settled at 2½ per cent. The referee's return was 2½ per cent. In this case, the ½ per cent. which the buyers lost by referring would make about £10 difference in the value of the parcel. The referee, on being informed what the other assays were, stated that two concordant assays by the battery process had given 3.60 per cent. copper. If the sample had contained this per cent. of pure copper it would have given 2½ per cent. by dry assay; and, as he stated that the dry and wet assays in 2½ per cent. pyrites by dry assay are as 2:3, it is very evident that his results by electro deposition are not reliable.

The following assays, in which the same assayers acted respectively, as vendors' assayer, buyers' assayer, and referee, again show the very variable results which are obtained by the Cornish assay:—

ASSAYS OF CUPREOUS PYRITES.

Vendors' Assayer.	Buyers' Assayer.	Wet Assays.	Referee.
		Works.	J. W. W.
2½	2½	3.07½	3.34
—	—	3.11½	—
—	2½ baro	3.17	3.19
—	2½ bare	3.29	3.25
			2½

In the first case the buyers gained by the low dry assay ⅛ per cent. on the parcel, equal to a money value of £19 10s.; in the second case, assuming 2½ per cent. to be a fair settlement, they lost £37 10s.; in the third case, assuming 2½ per cent. to be a fair settlement, they lost £17; or, if 2½ per cent. is regarded as a fair produce, £34 on the parcel.

That the margins I have assumed are correct, will be evident from the following assays, which were compromised:—

CUPREOUS PYRITES.

Wet Assays (J. W. W.)	Works	Another Works	Settled Produce.
Iodide Process.	Wet Assays.	Wet Assays.	
3.42	3.40	3.38	2½
3.15	3.17½	3.13	2½
3.15	3.11½	—	—
3.01	3.01	—	2½
3.03	—	—	—
3.31	—	—	—
3.33	3.27	—	2½
3.34	—	—	—

Again, it is well known that by buying the copper contents of pyrites by Cornish dry assay, burning off the sulphur and selling the copper contents of the burnt ore, an increase of copper is shown; and, if the copper is extracted, made into copper precipitate, and sold by Cornish assay, a much greater increase occurs.

Thus, in buying pyrites containing 3 per cent. copper by accurate wet assay, the settled produce will be $2\frac{1}{2}$ per cent. This will yield 70 per cent. burnt ore, containing 4.28 per cent. copper by wet assay, and $3\frac{1}{2}$ per cent. by dry assay.

	Tons.	Cwt.
Actual amount of copper present in 10,000 tons of pyrites containing 3 per cent. by wet assay	300	0
Copper paid for by dry assay, at $2\frac{1}{2}$ per cent.	212	10

70 per cent. of burnt ore from pyrites = 7000 tons.

	Tons.	Cwt.
Actual amount of copper present in 7000 tons burnt ore containing 4.28 per cent. by wet assay (4.287 per cent.)	300	0
Copper sold by dry assay at $3\frac{1}{2}$ per cent.	227	10

Increase in apparent amount of copper present	15	0
---	----	---

	£.	s.	d.
Money value of 10,000 tons pyrites copper contents on basis of Swansea sale, April 21, 1885, at $2\frac{1}{2}$ per cent.	3000	0	0
Money value of 7000 tons burnt ore, copper contents on same basis at $3\frac{1}{2}$ per cent.	5425	0	0

Increase in value of copper contents, £2425; or per ton of pyrites 1.85 shillings.

By converting the copper into precipitate, the apparent amount of copper is still more increased.

Thus, assuming 10 per cent. copper on the pyrites is lost in manipulation, or left in the burnt ore, we have 2.90 per cent. extracted from 10,000 tons of pyrites = 290 tons. By converting this into precipitate, 86 per cent. by dry assay, with 1.625 per cent. margin = 87.625 per cent. wet assay; or 100 of copper by dry assay is equal to 101.89 by wet assay. The 290 tons of pure copper extracted from the pyrites would give 330.95 tons precipitate, containing 86 per cent. by dry and 87.625 by wet assay, equal to 284.62 tons of fine copper by dry assay.

	Tons.
Fine copper purchased in pyrites, $2\frac{1}{2}$ per cent. by dry assay.	212.5
Fine copper sold in precipitates 86 per cent. by dry assay, 87.625 by wet assay	284.62
Increase in the amount of copper sold	72.12

CONTRACTS FOR THE SALE AND PURCHASE OF COPPER ORES, ETC.

As details of the method adopted by assayers in agreeing produces are not generally known, the following description may be of interest.

In the printed forms of contract provided for the purchase and sale of copper ores and products, it is stipulated that sealed samples shall be forwarded, — one by the sellers to a Cornish assay master, and another by the buyers to another Cornish assay master, who are to agree the produce — a third sample to be sealed by the samplers, and held by them as a reference sample.

A certain number of copper assayers in Cornwall and Swansea are recognised as Cornish assayers, and practically all the assays required for commercial purposes are made by them; but I have been informed very recently that in a few instances copper ores are being purchased in England on the results of wet assays.

The vendors' assayer, after assaying his sample, forwards his results to the buyers' assayer, who has also examined a sample, and then a reply is sent, naming a produce, and proposing a settlement. In most cases wet assays have been forwarded by the principals to their respective assayers for their guid-

ance, and it is understood that settlements must not be made, unless there is a certain margin between the wet and dry assays, without further reference to the principals; and in some cases wet assays are made by several analysts, before a proposed settlement is rejected or accepted. Possibly half a-dozen letters may pass before a settlement is effected. In the event of their not agreeing, each assayer alternately nominates three of the recognised assayers, and one of them is selected by the other as referee. The decision of the referee, whatever it may be, is held to be final and binding on all parties; but instances have been given in this paper where the referee's results have been seriously at variance with those of the other assayers.

Apart from the errors and inaccuracy of the dry assay, a very serious objection to the present system is that it is almost impossible to obtain a reliable private assay. Thus, assuming a sample to have been settled in the usual manner, and it is considered advisable to have the results of a third assayer. A sealed sample forwarded to an assay master, with weight of parcel, ex-ship, names of buyer and seller, practically informs him who has previously examined the parcel; and, as correspondence is frequently passing between the assayers, very little difficulty is experienced in obtaining the "settled produces" sent to the principals. Cases are known to me which prove that this is by no means a theoretical objection.

The copper ores raised in Cornwall and Devonshire are sold at ticketings held at Truro and Redruth. When a mine has a parcel of copper ore for sale, notice is sent to the sampler, who samples the parcel carefully, placing portions of $\frac{1}{2}$ lb. to $\frac{1}{4}$ lb. each in a number of small bags, which are sent to the smelter's assayers, who exchange produces and compare results. In many cases also samples are sent to the smelter's works, where they are tested by wet assay, and also assayed for silver. The results of the assays are forwarded to the smelters, who make a written offer on a ticket for the ore. These are handed in at the ticketings, the highest tender obtaining the parcel; but where two tenders are alike it is divided. After the sale the buyers' agent weighs over the parcel, the moisture is taken, and the actual weight calculated to 21 cwt. of dry ore per ton.

Ores, matte, etc., from abroad, were formerly largely imported into Swansea, and ticketings were held there. For some time past, however, large quantities of matte, ore, bar copper, etc., have been brought into Liverpool and disposed of by private contract. This has also been the case at Swansea, and in consequence the public ticketings or Swansea sales have been of rare occurrence, the last five being held on the following dates:—

1883	February 27, May 1, August 14, December 4.
1884	No public ticketing.
1885	April 21.

No ticketing since.

For the purpose of comparing the price of copper ores, or rather of "fine copper" in the ore, the "standard" is used. This is the price of one ton of fine copper in the ore—plus the "returning charges," the latter being calculated at 45s. per ton of ore (of $8\frac{3}{4}$ per cent. produce) for the Swansea sales, and 55s. per ton of ore for the Cornish sales, it being assumed that the extra 10s. per ton in the latter case is extra cost incurred in removing the ores from Cornwall to the smelter's works in Wales.

The following examples illustrate the method used in calculating the standard from the results of the Cornish ticketings:—

Rule.—Multiply the number of tons of ore by 55s. to obtain the total returning charges; add this to the money value of the sale, and divide the product by the weight of fine copper—the quotient is the standard for the sale.

Redruth Sale. September 4, 1884.

Average produce $6\frac{1}{2}$ 985-21cwt.
 Price per 21cwt., £2 12 6 Money, £2591 12 0
 Fine copper 63 tons 6cwt. = 63 $\frac{1}{2}$ tons.
 Standard £83 15 0 for $6\frac{1}{2}$ per cent.
 (55' - × 985) ÷ £2591 12 0
 63 3
 = £83 15 0

Truro Sale. September 18, 1884.

Average produce $5\frac{1}{4}$ 2289-21cwt.
 Price per 21cwt., £2 9 0 Money, £5597 7 6
 Fine copper 131 tons 16cwt. = 131 $\frac{1}{2}$ tons.
 Standard £88 4 0 for $5\frac{1}{4}$ per cent.
 (2289 × 55/-) ÷ £5597 7 6
 131 $\frac{1}{2}$
 = £88 4 0

The standard of the Swansea sales is calculated differently—in this case a variable returning charge, depending on the average produce of the ore at the sale being used. This average produce is obtained from what is termed the “settled list”—i.e., the produces agreed on at a conference by the smelter’s assayers, and which are kept as far as possible secret.

On examining the Swansea list of April 21, 1885, a column will be found headed “Produce.” The results inserted under this heading are those of assays made on behalf of the sellers, while the blank columns adjoining are for the smelter’s private assays, and the “settled” produces. Thus, while the total amount of copper by the Swansea list (April 21, 1885) amounted to 171 tons, 5cwt., 1qr. 15lb., the fine copper by the settled list was 167 tons, 17cwt., 1qr. 15lb., and as the number of 21cwt.-tons. of ore was 1541—the average produce was 10 $\frac{8}{9}$ 93 or 10 $\frac{1}{2}$ per cent. The variable returning charge for this percentage is £2 12s. 11d.—the standard being calculated as follows :—

Money value of sale £6154 15 6
 Fine copper, 167 tons 17cwt., 1qr. 15lb. = 167 $\frac{869}{1000}$ tons.
 (1541 × £2 12 11) ÷ £6154 15 6
 167 $\frac{869}{1000}$
 = £60 19 0
 Or approximately £61 0 0

The great distinction between the standards of the Cornish and Swansea ticketings, is that in the former the returning charge is constant, whatever the average produce of the sale; while in the Swansea sales the returning charge varies with the average produce of the sale, 45s. being the returning charge (R.C.) for 8 $\frac{3}{4}$ per cent. produce, and also that the calculation is made from the assayers’ settled list, and not from the produces given in the Swansea copper ore circular.

It must, however, be most distinctly understood that the “standard” is calculated from the prices paid for copper ores, and not the reverse.

The chief reason why I have entered into detail regarding these sales is that, until recently, contracts for the purchase of cupreous pyrites were in force, based on the price of copper ore at the Swansea ticketing immediately preceding the day of delivery; or, if a Swansea ticketing was held on that day, the price was to be calculated from it. This method is, however, now only used in one or two cases, the principal one being where the sulphur contents of pyrites are sold to alkali makers, the vendors taking back the burnt cinders for the extraction of the copper. The pyrites and burnt ores are examined by dry assay, and the value calculated from the standard of the last Swansea sale R.C. 45s.; but in this case it is simply used as a matter of form, for the apparent gain in the value of the copper is commuted to a definite payment per ton of pyrites burned.

The Swansea sales being now of rare occurrence, an interval of sixteen months elapsing between the

two last, and the price of Chili bar copper declining in the interval from £59 to £44, resulted in serious loss to buyers who had purchased on this basis. The prices of Chili bar copper, the standard of the two last sales, and the price of 2 $\frac{1}{2}$ per cent. R.C. 38s, were as follows :—

Swansea Sales.

	Dec. 4, 1883.	April 21, 1885.
Chili bar copper	£59 5 0	£44 1 0
Standard Swansea Sale	76 10 0	61 0 0
Price of 2 $\frac{1}{2}$ R.C. 38 - on basis of	0 19 6	0 13 0
Swansea sale		

A difference of 6s. 6d. per ton in the price of pyrites containing 2 $\frac{1}{2}$ per cent of copper by dry assay. This excessive difference in value rendered a change in the basis of valuation desirable, and large sales of pyrites were made, the value of the copper contents being calculated from the price of Chili bar copper in the following manner :—

The price of the pyrites to be calculated from the “settled” dry assays at the rate of one shilling per unit per ton for every five pounds in the price of Chili bar copper, good ordinary brands, cash price of 96 per cent., with a deduction of 1s. 6d. per unit from that figure.

Thus the price of 2 per cent. by this method, with Chili bar copper at £50 per ton, is 17s.

Another method, which is coming more into favour, is deduced from the price of Chili bar copper in the following manner :—The “standard” of Chili bar copper is calculated by means of the variable returning charge (V.R.C.), and from this the price of the ore is deduced.

I have previously mentioned that the standard of the Swansea sale is obtained by means of a V.R.C., depending on the average produce of the mineral sold. The method employed in calculating this is extremely simple, but it is not generally known even to buyers or sellers of copper ores. The 45s. Swansea returning charges is for 8 $\frac{3}{4}$ per cent only, others being derived from it in the following manner :—For each unit of produce 3s. 9d. is taken, with an addition of 12s. 2d., fractions of units being allowed for as below :—

	s. d.
1	0 5
2	0 11
3	1 5
4	1 10
5	2 4
6	2 10
7	3 3
8	3 9
Thus 8 $\frac{3}{4}$ %	
s. d.	s. d. 3%
(3 9 × 8) ÷ 12	2 2 10
	= £2 5s. 0d.

And other produces in a similar manner.

The returning charge for Chili bar copper 96 per cent. is thus—(3s. 9d. × 96) ÷ 12s. 2d. = £18 12s. 2d. This, added to the price of the metal, the product multiplied by 100 and divided by 96, gives the “standard.” If the price of Chili bar copper is £50 per ton, then

£	s.	d.
50	0	0
Returning Charge	18	12 2
	68	12 2
		100
96)		
	71	9 4 Standard.

From this the price of any produce is calculated by multiplying the standard by the produce and dividing by 100; the variable returning charge is subtracted from the quotient, and the remainder is the price at 45s. 0d. R.C. If the price is based on any other re-

turning charge *lower* than 45s. per ton, the difference is *added* to the price of the ore, while if the returning charge is higher it is deducted from it.

The price of cupreous pyrites containing $2\frac{1}{2}$ per cent. of copper by dry assay, by the two methods of valuation based on the price of Chili bar copper at £40 per ton 96 per cent., is as follows:—

First method, 1s. per unit for every £5 in the cash price of Chili bar copper 96 per cent., with a deduction of 1s. 6d. per unit from this figure,

	s.	d.
Deduct	8	0
	1	6
	6	6
		$2\frac{1}{2}$
	11	$7\frac{1}{2}$

Second method by variable standard at 38s. returning charge—

	£	s.	d.

---	---	----

Add difference
between 45/ and 38/ R.C.

0	7	0
---	---	---

0	13	10
---	----	----

The comparison of prices at the time of the last Swansea sale is also instructive. The standard of the sale was £61 0s. 0d. The average price of Chili bar copper, 16—30th April, 1885, was £44 1s. 0d., variable standard £65 5s. 4d., and the price of $2\frac{1}{2}$ per cent. copper at 38s. R.C. by the various methods is as follows:—

	By first method 1/ per unit for every £5 in C.B. copper, etc.	s.	d.
R.C. 38/	By Chili bar variable standard	15	7
	By Swansea sale	13	0

The two methods of fixing prices on the basis of the price of Chili bar copper give the following results with different produces:—

Price of C.B. Copper, £40 0s. 0d.

	1%	2%	3%
1/ per unit method	6s. 6d.	13s. 0d.	19s. 6d.
Variable standard method R.C. 38/	3s. 3½d.	11s. 9d.	£1 0s. 2½d.

From the fact that Swansea sales are now of comparatively rare occurrence, and also that the basis on which the copper contents of pyrites have been valued has been found very unsatisfactory, it seems to me that in new contracts a much more reliable method may be devised. Thus the uncertainty, annoyance, and often heavy pecuniary loss, caused by the discordant and unreliable results of the dry assays, may be avoided by taking the wet assays made by the iodide process as a standard method, and deducting a definite fixed margin (varying with the percentage) from these results representing the difference between the wet and dry assays, the remainder being charged as copper by either of the methods given previously. An illustration will show more clearly how the basis would be arrived at. A parcel of pyrites contains 3·00 per

cent. of copper by wet assay—from this a deduction of $\frac{1}{3}$ per cent. or '875 would be made, leaving 2·125 or $2\frac{1}{4}$ per cent. on which produce payment would be made. For pyrites assaying $3\frac{1}{2}$ to 4 per cent. of copper by wet assay, I would deduct 1 per cent. margin.

The advantage of this method would be that perfectly reliable results, much more trustworthy than dry assays, would form the basis of value, and the buyer knowing exactly the amount of copper he would obtain, could make his calculations regarding price and profit with more certainty than at present. Again, it is a well-known fact that much dissatisfaction exists regarding the "margin" between the wet and dry assays, buyers contending that it is not what they have been led to expect, and on which they have based the price payable under their contracts; while selling assayers are complaining that they are checked in all directions, and that it is simply a question of dry assays, and buyers must look after their own interests when fixing prices. This is especially the case with rich copper mattes, and much friction has occurred regarding the settlements of these products.

An objection may be urged that copper extractors would still have to sell their precipitates by dry assay; but I think there can be no doubt if once a good and reliable process of wet assay is introduced for contract purposes, it will be used for buying and selling all classes of copper products, and the fact that by making a certain deduction to be termed the "margin" from the wet assays, the remainder can be used as an equivalent to the present dry assay, no other changes would be necessary, renders this method a most desirable one.

In those cases where the sulphur contents only of pyrites are sold, the burnt ores being returned to the vendors for the extraction of the copper, careful wet assays would supply the necessary check on the quantity of copper sent to and returned from the buyers of the sulphur contents.

Copper ores, mattes, precipitates are generally sold at a certain price per unit of copper determined by dry assay, but sometimes this is varied in the following manner: The price shall be based on 8s. (or other sum) per unit for 20 per cent. (or other produce), and if the produce varies from this a *pro rata* augmentation or deduction shall be made.

Required—price of 12 per cent. at 8s. per unit for 20 per cent.

	£	s.	d.
$8/ \times 20$	8	0	0
R.C. ($3/9 \times 20$) + 12×2	4	7	2
	12	7	2
			100
20)			
Variable	61	15	10
Standard			12
100)	741	10	0
	7	8	3
Variable R.C. 12%	39	12	2
Price of 12%	4	11	1

Or 7s. 7d. per unit.

CHILI BAR COPPER CONTRACTS.

Chili bar copper is sold on the basis that it shall contain not less than 96 per cent. pure copper, and the wording of the printed forms of contract, which were adopted by the London Metal Exchange so lately as August, 1883, show that details regarding the methods of assay are even yet not known to

* This method, making an allowance from the results of wet assays, is used in the United States, where wet assays are invariably used for determining the value of copper in ores and products. See Journal of the Society of Chemical Industry, January, 1885, p. 30.

of the day of sampling; interest at the rate of 5 per cent. per annum to be allowed for any earlier payment; also rent up to prompt date.

"Any dispute on this contract to be settled by arbitration according to Rule 2.

"Rules.

"No. 1. Members are responsible to each other only for the fulfilment of every Contract in which another principal is not mentioned by name.

"No. 2. All disputes arising upon Contracts shall be referred to two arbitrators, one to be chosen by each party in difference, the said arbitrators having power to call in a third in case they shall deem it necessary. In the event, however, of one of the parties appointing an arbitrator, and the other refusing, or neglecting to do so, for seven days after notice in writing of the appointment (such notice being delivered personally or left at the usual place of business of such other party), or in case of the death, refusal to act, or incapacity of either of such two arbitrators; then upon application of either of the disputing parties, the question in dispute shall stand referred to the arbitrator named by one of the contending parties and another arbitrator, who shall be appointed by the Committee of the London Metal Exchange, at a meeting convened by notice, and at which not less than three members shall be present. In case the two arbitrators appointed as aforesaid, whether originally or by way of substitution, shall not within fourteen days after their appointment agree to an award or choose a third arbitrator, then the Committee of the Metal Exchange, at a meeting constituted as herein before provided, shall appoint a third arbitrator, and shall, in case of death, refusal to act, or incapacity of any of such three arbitrators, from time to time substitute a new arbitrator or arbitrators in the place of the arbitrator or arbitrators so dying, refusing, or incapacitated. In making their reward the arbitrators shall state which party or parties are to pay expenses of arbitration, and the award of two arbitrators, in writing, shall in every case be conclusive and binding on the parties to the arbitration.

"No. 3. The prompt on arrival Contracts shall be fourteen days from notice of final passing of landing scales, except on Chili Bars, which shall be fourteen days from date of sampling, of which due notice shall be given. No notice of final passing of landing scales or sampling shall be valid unless the warrants are ready at time of such notice.

"No. 4. Sellers of arrival parcels shall advise buyers of any information which they may have from the shippers in regard to the weights or otherwise as soon as received.

"No. 5. Sellers shall tender documents not later than 3.30 p.m. on the prompt day; except the prompt fall on Saturday, when the tender shall be made by 2 p.m.

"No. 6. If the sellers fail to deliver on the prompt day, the buyers shall be entitled to buy in against them, either publicly or privately, on the next morning's 'Change; or if the buyers fail to take delivery on the prompt day the sellers shall be entitled to sell out against them, either publicly or privately, on the next morning's 'Change, and the person or persons in default shall at once pay the loss, if any, by repurchase or re-sale, or receive the profit, if any, in like manner. The buyers or sellers, as the case may be, who claim to act under this clause shall send written notice on the prompt day, to the person or persons in default, that action in conformity therewith will be taken.

"No. 7. When buyers and sellers agree to settle outstanding Contracts between them by a difference account, such differences shall be calculated on the exact Contract weight without any deduction whatsoever therefrom.

"a. All imports of Chili Bar Copper are to be weighed in drafts of 5 bars each, and warrants issued as far as possible for 25 tons each, and one for the balance, if any—e.g., taking an import of 99 tons, three warrants would be issued for 25 tons each, and one for balance of 24 tons; or, taking an import of 101 tons, then four warrants of 25 tons each and one for the balance of 1 ton. An assay certificate to be attached to each warrant. On all Contracts for Chili Bars, Warrants may not be tendered for fractional parts of 25 tons unless they together make up a quantity of 25 tons, and lying at one port.

"c. On all Contracts for Foreign Copper, one per cent. more or less on gross weight may be delivered, and at Contract price, but if the excess or efficiency exceed one per cent., then the whole difference in weight, without deduction of draft, is to be settled at the mean official quotation of the Committee of the

Metal Exchange of the evening previous to the day of settlement. A delivery shall be accepted as good so long as the deficiency or excess, as the case may be, does not exceed five per cent. on the gross weight tendered.

"d. All Contracts for Foreign Copper, unless specially arranged otherwise, shall carry a prompt of 14 days, and the buyers shall have the right to take up the warrants on any day before that prompt date under allowance of interest at 5 per cent. per annum; also rent for the unexpired portion of that prompt, but notice of such uplifting must be given at latest by twelve noon on the day on which delivery of the warrants is required. If the sellers fail to deliver as per notice, they shall allow interest as if the warrants had been duly delivered on the day required; but sellers shall not be entitled to more than one clear day's grace.

"e. Chili Bar warrants without assay certificates may not be refused, but the buyers need only pay for them on account, say within two per cent. of the invoice amount; the balance to be paid on production of the assay certificate. No new brand of Chili Copper shall be tendered on a Contract for G.O.B.'s unless accompanied by a certificate of two Cornish assayers that the quality is *good ordinary*. If the quality be thus certified as "good ordinary," then such brand shall be considered as a lawful tender, but if it be not up to said standard it may be rejected, and the sellers shall provide a similar quantity of a recognised brand within 24 hours of day of notice of such rejection, and which must be given by buyers in writing. Should the tender be made on an "arrival" Contract then the prompt shall date on or from the day the certificate is tendered to the buyers according to terms of Contract."

THE ASSAY OF GOLD IN BAR COPPER.

Bar coppers containing silver and gold are often bought and sold in the English market, and the results of various assayers have frequently been compared with my own assays.

The general tendency is for the gold produce to be low, sometimes to a serious degree, even in the results of practising assayers. I believe this is due to some extent to the insufficient weight of material operated on; for a long time I could not persuade my then employers to use more than $\frac{1}{2}$ oz. of copper chips for assay; in this case an error of '001 grain in the weight of the gold would amount to 3dwts. of gold per ton of copper. Subsequently I made assays on 1oz. of chips; in this case '001 grain, representing 1½dwts. per ton; but by careful weighing this could be reduced one half, or to 18 grains per ton.

I was informed that one assayer made his gold assays on 100 grains of copper chips. In this case '001 grain in the weight of the gold, representing 6½dwts. per ton; and it must be remembered that the value of this gold varies from 2s. to 3s. 6d. per dwt.; hence the necessity for careful and accurate work.

The following are results obtained by other assayers and myself examining samples for commercial purposes:—

Half-ounce assays. Per ton of 2240lb. avoird.	J. W. W.			Buying Assayer		
	oz.	dwts	grs.	oz.	dwts.	grs.
	1	0	23	+1	1	12
	1	3	21	+1	1	12
	0	8	23	:0	8	0
1 ounce assays	1	3	21	+1	1	12
	0	18	16	+0	17	0
No value	0	6	17	+0	8	0
	0	6	17			
	0	19	9	+0	16	0
	0	4	18		17	0
No value	0	4	16	+0	3	0
	1	3	21	+1	4	12
	0	12	6	+0	7	12

In this case the buying assayer first offered 7dwts 12 grains, then 8dwts., but would not name referee when requested. He then offered 10dwts., and

finally settled at 11dwts. If this sample had been settled as the buying assayer wished, the gold value would have been nil, at 11dwts. the value was approximately £25.

8	11	7	8	10	0	settled
8	5	15	8	0	0	„

HALF OUNCE ASSAYS—

1	0	21	0	11	0	1	4	12
0	11	22	0	8	0	0	12	0
0	11	22	0	8	0	0	16	8

The following series are also interesting $\frac{1}{2}$ oz. trials :

	<i>J. W. W.</i>			<i>Buying Assayer.</i>			<i>Referee.</i>		
	oz.	dwt.	grs.	dwt.	dwt.	oz.	dwt.	grs.	
<i>a.</i>	1	5	9	13	0	1	0	12	
<i>b.</i>	0	11	22	6	12	9	0		
<i>c.</i>	6	11	22	6	12	9	0	16	
re-assay	0	16	10	6	12	9	0	12	
<i>d.</i>	0	11	22	6	12	9	0		

The buying assayer in this case suggested that one of the samples *b*, *c*, *d*, should be referred, and that the result should be taken to represent all three parcels ; this was agreed to if he would refer *c*, and the result is shown above.

The following is a most serious case :—

	oz.	dwt.	grs.	
J. W. W.....	12	6	9	
Buyers' assayer & re-assay	10	11	0 ¹ / ₂	loss, per ton difference in
But will settle at	11	10	0 ¹ / ₂	value of gold by these assays.
Referee's return	12	1	0	

In this case the difference in gold value between the buyers' assay and the referee's return is £4 14s. 6d. per ton, while the difference in the referee's return and my assay amounts to 18s. 9d. per ton.

The assays marked + were made by a London assayer, those marked ‡ by assayers employed in works, those marked || by copper assayers, but not the same assayer in all cases, while my initials indicate assays made by me.

It is evident from the results given that the assays of gold in bar copper are not conducted as carefully as they should be, taking the value of the metal into consideration.

In conclusion, I wish to express my opinion that the discrepancies I have pointed out are due in most cases to careless work and the use of inaccurate methods of analysis and assay, and in a very minor degree to errors of sampling. The results I have brought forward are the actual figures which have been obtained in the examination of samples for commercial purposes. I desire also to express my thanks to those gentlemen who have assisted me in the preparation of this paper, either by furnishing me with the forms of contract used in the copper trade, the respective prices of gold and copper, or with the methods of assay used in their laboratories.

Finally, I would submit the following propositions :—

(a) That the temperature at which the moisture in copper ores, etc., is determined, should be more clearly defined than it is at present.

(b) That for the wet assay of copper in ores and products generally, the iodide process (E. O. Brown's modification) is the most reliable and accurate, but

that the electro-deposition method may also be used in cases where it is desirable to have results of *two separate and distinct processes*, it being noted that in certain cases other metals are deposited with the copper.

(c) That the Cornish process of dry assay is very inaccurate and misleading, and is also liable to serious variation in the hands of experienced operators : these reasons, together with the fact that it is extremely difficult to get reliable private assays, render its use undesirable.

(d) That in cases where the sulphur contents of pyrites are sold to alkali works, the burnt ores being returned to the vendors, an accurate wet assay forms the best check on the copper contents of the ore delivered to and received from the alkali works.

(e) That a more suitable basis for the valuation of copper in ores and products may be found in wet assays made by the iodide process, deducting an allowance (or "margin" to be agreed on by vendors and purchasers) from these results, thus bringing down the percentage to the dry assay produce, and calculating the value by methods at present in use, or given previously in this paper.

(f) That many assays of gold in bar coppers, made by recognised assayers, are very inaccurate.

3rd March.—Mr. James Longmore : "Researches on the Colouring Matter and Mucilage of Cotton-seed Oil ; with a Description of a New Method for Recovering the Position lost during the Refining Process."

Meeting held Wednesday, 13th January, 1886, at University College, Ashton Street.

THE PRESIDENT IN THE CHAIR.

THE CHAIRMAN announced the resignation of Mr. E. G. Ballard as Hon. Local Secretary, and the election of Mr. W. P. Thompson in his stead.

On the motion of Mr. NORMAN TATE, seconded by Dr. CAMPBELL BROWN, it was resolved to form a committee to make arrangements for the reception of the Society at the Annual Meeting in July.

MR. ALEX. WATT made a communication on "An Electrically-driven Centrifugal Machine for Laboratory Use," and exhibited it in action. (See Journal, vol. iv. p. 754.) The discussion turned chiefly on the practical uses of centrifugal machines.

Dr. CAMPBELL BROWN, after pointing out the cleanliness and easy transmission of electricity as a motive power, asked if the author could give them any notion of its relative cost compared with other sources of power?

The CHAIRMAN said that twenty years ago he had tried centrifugal machines for separating the red

liquor from caustic salts, but the result was unsatisfactory.

Mr. SIMPSON agreed with the Chairman, and said that they now used a filter-press for the purpose, which turned out some twenty tons a day. The centrifugal machine was also quite useless for lime-mud.

Dr. CAMPBELL BROWN admitted that centrifugal machines were no use for gelatinous precipitates, such as hydrated oxide of iron.

Mr. WATT suggested that a centrifugal machine was better adapted for crystals than a filter-press, as the latter was liable to crush them.

Mr. SIMPSON dissented from this view.

The CHAIRMAN said that, according to the author's calculation, a centrifugal machine would turn out ten tons of crystals per day of ten hours. Filter-presses could not be compared with centrifugal machines, as they were each used for entirely different classes of substances. In his own new process for making potassium chlorate, by means of magnesia in place of lime, he used a centrifugal machine to free the crystals of magnesium chloride from mother-liquor, and at least five tons a day could be thus obtained. The men engaged on the process were not solely occupied in working the machine, so that he could readily accept the author's estimate of the work capable of being done. For caustic salts or lime-mud, undoubtedly the machine was less suitable, but for crystals of magnesium chloride he was quite satisfied with its efficiency.

Dr. HURTER said that the machines at the works of his firm were six feet in diameter, and were placed on the first floor of the house. The vibration was, however, so great that he had to reduce the speed to from 300 to 400 revolutions per minute. Two of these machines could dry about 300 tons of crystal carbonate per week, but he agreed that their efficiency depended largely on the class of substance dealt with. For instance, they were quite useless with lime mud.

Mr. WATT, in reply to Dr. Campbell Brown, said that the cost had not been ascertained, but he might point out that in the case of the Weston suspended drum machine, the electrically-driven one worked much more steadily than that driven by belting. In reply to Mr. Simpson, the 30in. machine would turn out about 1½ cwt. of dried sugar crystals every five minutes. At the same time, some kinds of sugar took about a quarter of an hour to dry.

A COMMUNICATION on "Some Experiments on Purifying Distillable Oils" was then read, in the discussion on which the President, Mr. Norman Tate, Dr. Campbell Brown, Mr. W. P. Thompson, and others took part.

Meeting held 3rd February, at University College, Ashton Street.

MR. J. CAMPBELL BROWN IN THE CHAIR.

THE LOCAL SECRETARY exhibited samples of fibre, yarn, flooreloth, trouserings, and broadcloth made from peat-fibre by a new French process.

Dr. OLIVER LODGE then read a paper on "The Electrical Deposition of Dust and Smoke, with Special Reference to the Collection of Fine Metallic Fume, to the Possibility of Diminishing the Escape of Solid Matter from Chimneys by the Electrification of the Air inside them, and to the Electrical Purification of the Atmosphere." A copy of this paper, with the discussion thereon, will appear in a future number.

MEETINGS, SESSION 1885-86.—First Tuesday in each Month, at 7 P.M.

Notices of papers and communications for the meetings to be sent to the Local Secretary.

FURTHER NOTES ON THE METHODS OF EXAMINING AND CHEMISTRY OF FIXED OILS.

BY ALFRED H. ALLEN.

In a paper read before the London Section of the Chemical Society of Industry about three years since, I reviewed the general condition of our knowledge of the chemistry of fixed oils, and described some of the more definite methods applicable to their assay and analysis. The subject has made considerable advances since that time, and I have been at some trouble to collect and collate the results of various workers. The paper which I propose to lay before you this evening will, therefore, be the result of this collation, supplemented by observations of my own in cases where the information at hand seemed insufficient.

Specific Gravity of Oils.—A very satisfactory method of determining the density of fixed oils is by means of Westphal's *hydrostatic balance*. A counterpoised thermometer, suspended from a piece of thin platinum wire, is attached to one end of a graduated lever. On immersing the thermometer in a liquid, it loses a certain weight. The equilibrium is restored by hanging on the lever a series of riders, which are adjusted in weight so as to make the reading very simple.* The plummet displaces exactly 5cc. of liquid, and hence the weight required to restore equilibrium is that of 5cc. of the fluid of which the density is required. Differences of 0.2 are appreciable, so that the indications are equal in delicacy to those of the specific gravity bottle, and considerably more accurate than the readings of a hydrometer. As the employment of a thermometer as a plummet renders the instrument unsuited for determinations of density at 100° C., or other high temperatures, I substitute, in such cases, a plummet of thick glass rod, having a displacement of exactly 5cc.

It is evident that a special balance and riders for taking densities by a plummet are by no means essential. If a plummet of known displacement be suspended from one arm of a balance and duly counterpoised, on immersing it in a liquid it will lose a portion of its weight equal to the weight of an equal volume of the liquid employed; and this loss being ascertained by adding weights sufficient to restore equilibrium, the specific gravity of the liquid will be found by dividing the weight in grammes employed by the volume of the plummet in cubic centimeters. If a plummet of 10cc. displacement be employed, the density of the liquid will be one-tenth of the weight in grammes required to restore equilibrium.

* Westphal's balance can be obtained from Messrs. Beeker & Co., Maiden Lane, E.C.

The glass plummet may be brought approximately to the desired bulk by noting its displacement. Its specific gravity is then carefully determined by weighing it in distilled water, when the exact weight of 5 or 10cc. is readily calculated, and it is brought to this weight by careful grinding or filing.*

The use of a plummet of exactly 5 or 10cc. displacement facilitates calculation, but in its absence a plummet of any known measure can be employed, and this measure can be ascertained by dividing its weight in grammes by its specific gravity. The weight lost by the plummet on immersing it in any liquid, divided by the measure of the plummet, gives the specific gravity of the liquid.

My experience fully convinces me that the archimedeal or plummet method of taking the specific gravities of liquids deserves a wider application than it has hitherto received.

In my last paper I pointed out that the specific gravity of an oil was by no means an unmeaning character, but was a definite indication of its nature and chemical constitution. Thus, sperm and bottle-nose oils, which have the constitution of waxes, and are not glycerides, like the majority of fixed oils, have the lowest specific gravity. There is a great gap between these and the animal and vegetable oleins or non-drying oils, as represented by olive, almond, and lard oils. Rape oil may be classed in this group, but its constitution is sensibly different from that of the majority of vegetable oils. The drying oils, again, as typified by linseed oil, are sensibly denser than the non-drying oils; while castor oil exceeds all other natural fixed oils in density, and exhibits peculiarities in its physical properties and constitution which sharply distinguish it from almost all other natural oils.

I may here point out that the density of an oil is liable to be very materially altered by certain treatment, or even by keeping. Some three years ago I examined a sample of porpoise oil, which then had a density of 920; the sample now has a density of 926, though the proportion of free acid is not very materially increased. Another portion from the same sample, kept under different conditions, has now a density of 932. In all probability these changes are due to oxidation and are analogous to the change now brought about in rape oil, cottonseed oil, linseed oil, etc., which by a process of regulated oxidation are caused to acquire a density as high as 960; in that respect, as well as in their viscosity, simulating closely castor oil. These "blown oils," as they are called, are now manufactured as substitutes for castor oil, though, unlike the latter, they are perfectly miscible with mineral oils; but I am not prepared to say that their use is an advantage in other respects.

It is well known that butter fat, cocoa nut oil, and other fats containing the glycerides of lower fatty acids, are denser than lard, butterine, and similar fats not containing sensible quantities of such glycerides. The difference, however, is not very great; and in order to observe it satisfactorily, it is necessary to take the density of the fat in a molten condition. A temperature of 100° F. was adopted by Dr. J. Bell, but Mr. Charles Esteourt, in 1866, recommended that the fat should be heated to the boiling-point of water, and in my last paper I strongly urged that the density should be taken at the latter temperature, and recommended a Sprengel-tube as a suitable instrument for the purpose. Extensive experience of this method since the publication of my last paper has fully

confirmed the favourable opinion of it I then expressed. It enables one to compare the densities of all fats and waxes when in a fluid state; and only those who have tried have any idea how difficult it is to obtain concordant figures for the densities of waxes and similar bodies when the experiments are made on the solid substances. I have, however, in all cases where there is sufficient substance at disposal, abandoned the use of the Sprengel-tube in favour of the plummet, the use of which leaves nothing to be desired on the score of rapidity, accuracy, or ease of manipulation. The application of the Westphal balance to the determination of the density of butter and other fats at the boiling-point of water was, however, originally recommended by Mr. Charles Esteourt (*Chem. News*, xxxiv. 254), the details of the manipulation being further described by Mr. J. Carter Bell (*Chem. News*, xxxviii. 267). These chemists, who have habitually employed the method, immerse the tube containing the fat to be examined in a bath of molten paraffin, which is kept at a constant temperature by an outer vessel of boiling water. In my experiments, I have abandoned the intermediate bath of paraffin as unnecessary, and employ a cylindrical copper bath, the top of which is closed and perforated by two orifices. One of these is fitted with an upright tube, which serves to carry the steam away from the neighbourhood of the balance; while into the other the tube containing the fat fits tightly, the joint being made perfect by a ring of

cork or indiarubber. Any of the usual arrangements for keeping the water at a constant level can be employed, if desired, but I have not found this requisite.

The following table gives the densities, as determined in my laboratory, of a number of samples of oil at the temperature of boiling water. Some of the observations were made with the Sprengel-tube, and others by the plummet; but, in each case where both methods were employed, the results showed such a close concordance that I consider it a matter of indifference, so far as the figures are concerned, which method was used. In most cases, the density of the same sample was taken at the ordinary temperature in addition, these results being in some instances obtained by a hydrometer:—

* Mr. E. Casella, of 147, Holborn, E.C., supplies accurately-adjusted glass plummets and counterpoises for employment with an ordinary balance.

SPECIFIC GRAVITIES OF OILS, ETC.; WATER AT 15.5° C. (= 60° F.) = 1000.

OIL.	At 15.5° C. (= 60° F.)	At 98° to 99° C. (= 209° to 210° F.)
Arachis oil	922*	867.3
Rape oil	915*	863.2
Neatsfoot oil	911*	861.9
Cotton-seed oil	925*	872.5
Sesamé oil	921*	867.9
Cocoa-nut oil	926.2	871.0
Niger-seed oil	927*	873.8
Linseed oil	935*	880.9
Castor oil	965.5	909.6
Whale oil	950.7	872.5
Porpoise oil	926*	871.4
Seal oil	924*	873.3
Cod-liver oil	927.5	874.2
Menhaden oil	932*	877.4
Sperm oil	883.7	830.3
Doegling (Bottle-nose) oil	880.8	827.4

The next table shows the specific gravity, at two different temperatures, of various molten fats and other bodies which are solid at the ordinary temperature. The densities were ascertained by the plummet method, and in each case the observations at the two different temperatures were made on *the same sample* of the substance. A column is added showing the difference in density corresponding to a change of 1° C.

FAT, ETC.	Specific Gravities of melted Fats, etc.; Water at 15.5° C. (= 60° F.) = 1000.	Difference for 1° C.
Palm oil	893.0 at 50° C. 858.6 at 98° C.	.717
Cacao butter	892.1 at 50 857.7 at 98	.717
Japan wax	901.8 at 60 875.5 at 98	.692
Tallow	895.0 at 50 862.6 at 98	.675
Lard	898.5 at 40 860.8 at 98	.650
Butterine	898.2 at 40 859.2 at 98	.672
Butterfat	901.1 at 40 867.7 at 99	.617
Cocoa-nut oil	911.5 at 40* 873.6 at 99	.612
Palm-nut oil	911.9 at 40* 873.1 at 99	.657
Spermaceti	835.5 at 60 808.6 at 98	.716
Bees' wax	835.6 at 80 822.1 at 98	.750
Carnaúba wax	850.0 at 90 812.2 at 93	.375
Stearic acid (commercial)	859.0 at 60 830.5 at 98	.770
Oleic acid (commercial)	903.2 at 15.5 818.4 at 99	.656
Paraffin wax	780.5 at 60 753.0 at 98	.724

* The samples of cocoa-nut and palm-nut oil were old, and had been frequently melted. Some time previously they showed densities notably less than those stated in the table. The rate of expansion of carnaúba wax requires verification, as the temperatures at which the density was taken differed by 8° C. only.

It will be observed that I have stated the densities recorded in the foregoing tables as those obtained at a temperature of 98° to 99° C. In my laboratory, water ordinarily boils at 99° C., and repeated observations have shown that oil immersed in a vessel of boiling water rarely reaches a temperature exceeding 98.5° C. This result is a confirmation of the experience of Mr. Estcourt.

Coefficients of Expansion of Oils.—It is evident that the density of a particular sample of oil being known at two different temperatures, we have the means of calculating the rate of its expansion by heat. Assuming the oils when immersed in boiling water to have had a uniform temperature of 98½° C., the difference between their density at that temperature and at 15½° is due to the expansion through 83; dividing, therefore, this difference by 83, we get a series of figures representing the mean rate of expansion of the different oils for a rise of temperature of 1° C.†. The rates of expansion for the molten fats, etc., have already been given; those for the oils fluid at ordinary temperatures are expressed in the following table. Those figures to which my name is attached are calculated from the densities already given; but I have also appended the independent results of some other observers.

NATURE OF OIL.	Correction for 1° C.	OBSERVER.
Sperm oil618	A. H. Allen
Bottle-nose oil613	"
Whale oil697	"
"722	C. M. Wetherill
Porpoise oil654	A. H. Allen
Seal oil615	"
Cod-liver oil616	"
Menhaden oil651	"
Neatsfoot oil625	"
Lard oil653	C. M. Wetherill
Olive oil629	C. M. Stillwell
Arachis oil655	A. H. Allen
Rape oil620	"
Sesamé oil624	"
Cottonseed oil629	"
Nigerseed oil637	"
Linseed oil649	"
Castor oil653	"

From an inspection of the figures recorded in this and the preceding tables it appears (1) that the rates of expansion of the fluid fixed oils are not sufficiently different to be of any value for their recognition; (2) that, of the fluid fixed oils examined, all, with the single exception of whale oil, expand sensibly equally for equal increments of heat, or at least the figures obtained do not show greater variations than would probably be observed between different samples of the same oil; (3) that, with the exception of whale oil (the high figure for which is confirmed by an independent observer), the correction in density for the

† Thus, a sample of rape oil was found to have a density of 915.0 at 15½° C., and of 863.2 at 98° C., the difference being 51.8. Dividing the last figure by 82.5, the difference between the temperatures at which the observations were made (98.0–15.5 = 82.5), the figure .628 is obtained as the correction to be made for a variation of 1° C. from the standard temperature.

fluid fixed oils mentioned in the last table may safely be taken at '64 for each degree Centigrade, or '35 for each degree Fahrenheit* ; (+) the rate of expansion of the solid fats and waxes, when in a molten state, is not ascertained with such a degree of accuracy as in the case of the oils liquid at ordinary temperatures, but in most cases is sensibly higher than that of the oils of which olein is the leading constituent, this difference extending to free stearic and oleic acids.†

It is evident that the coefficient of expansion of an oil may be deduced by dividing the temperature-correction by the density. Thus, the coefficient of expansion of olive oil will be $\frac{.646}{.916} = .000715$. This figure may be corrected for the expansion of the glass plummet if a very accurate result be desired.

Viscosity of Oils.—The determination of the viscosity of oils is a question of great practical interest, and one on which I should have liked to have entered in some detail, were it not that a paper dealing exhaustively with the whole subject is to be read before the London Section of this Society at an early date by Mr. Boverton Redwood. I shall therefore merely exhibit the new form of viscosimeter devised by Mr. Redwood, and which bids fair to become the recognised standard instrument of the future. For many purposes, however, and especially as a convenient test by oil merchants, I think an instrument on a different principle is likely to grow in favour. It consists of a simple arrangement by which a small paddle-wheel (actuated by a falling weight) is caused to revolve in the sample of oil, maintained at a definite temperature by an outer vessel of water. The manipulation is extremely simple, and the results expressed by the number of seconds required by the weight to fall through a given space are remarkably constant.‡

Bromine and Iodine Absorptions of Oils.—Dr. E. J. Mills and his coadjutors have described a method of determining the proportion of bromine absorbed by fixed oils to form bromo-additive compounds (see *Jour. Soc. Chem. Ind.* ii. 435, and iii. 366), and Baron Hübl (*Jour. Soc. Chem. Ind.* iii. 641) has investigated the percentage of iodine which various oils assimilate. The amount of halogen taken up may be considered as a measure of the unsaturated fatty acids (or their glycerides) present. Thus, the acids of the acetic or stearic series exhibit no tendency to combine with bromine or iodine under the conditions of the experiments, while the acids of the acrylic or oleic series assimilate two, and the acids of the linoleic series four atoms of the halogen. In order to facilitate comparison between the results of Mills and Hübl, I have multiplied the bromine absorptions of the former chemist by $\frac{127}{80}$, so as to obtain the equivalent

iodine absorptions, and in the following table have placed the figures so obtained in juxtaposition with the experimental numbers for iodine absorptions obtained by Hübl.

IODINE AND BROMINE ABSORPTION OF OILS.

NAME OF OIL	Mills' Bromine Absorption	$\times \frac{127}{80} =$ Iodine Absorption	Hübl's Iodine Absorption
Almond	26.3	41.8	98.4
Peach-kernel ..	25.4	40.4	—
Apricot-kernel ..	—	—	100.0
Olive-kernel ..	—	—	81.8
Olive	54.0—60.6	85.9—96.1	82.8
Earth-nut (Arachis) ..	46.2	73.3	103.0
Rape	69.4	110.4	100.0
Sesamé	47.4	75.2	106.0
Cotton-seed	50.0	79.5	106.0
Poppy-seed	56.5	89.9	136.0
Hemp-seed	—	—	113.0
Linseed (raw) ..	76.0	120.8	158.0
Linseed (boiled) ..	102.1	162.8	—
Castor	58.3	92.7	81.4
Cod-liver	83.9	133.4	—
Ling-liver	82.4	131.0	—
Shark-liver	81.4	131.2	—
Seal	57.3—59.0	91.2—95.3	—
Whale	50.9	80.9	—
Bottle-nose	48.7	77.4	—
Palm	34.8—35.4	55.3—56.3	51.5
Cocoa-nut	5.7	9.1	8.9
Cacao butter	—	—	34.0
Japan wax	1.5—2.3	2.4—3.7	1.2
Butter fat	24.5—27.9	38.9—44.1	31.0
Buttarine	36.3—39.7	57.7—63.1	55.3
Lard	37.3	59.3	59.0
Tallow	—	—	40.0
Bees' wax	0.0—0.54	0.0—0.86	—
Carnauba wax ..	33.5	53.3	—

These figures are very instructive. They indicate that the drying oils (containing linoleic acid) assimilate the largest proportions of the halogen, and their capacity in this respect might probably be employed as a measure of their drying powers. The fish-liver oils, however, fully equal the vegetable drying oils in their assimilating power for halogens. The results of Hübl may be regarded as, in the main, confirming those of Mills, but there is a striking exception in the case of almond oil, which is usually supposed to have a very similar composition to olive oil; but if Mills' figures be correct, this is clearly not the case, and almond oil must consist largely of glycerides of saturated (solid) fatty acids. Similarly, oils from peach-kernels and apricot-kernels might be expected to be of substantially similar nature; but this does not appear by the

* Thus, if a sample of oil has been found to have a density of 920.7 at 22° C., the density at 15.5° C. may be found in the following manner:—

$$\begin{array}{r} 22.0 \\ -15.5 \\ \hline 6.5 \times .61 = 4.16 \\ +920.70 \\ \hline 924.86 \end{array}$$

The establishment of the fact that the rate of expansion of the majority of fluid oils is practically identical, will greatly facilitate corrections for temperature in cases where it is not convenient to ascertain the density at exactly the standard point.

† Owing to the enormous contraction undergone by many waxes and fats in the act of solidification, in the solid state they are considerably denser than the fluid fixed oils. Thus, solid beeswax is as dense as castor oil, but in the molten state it is much lighter.

‡ The apparatus has passed through several stages of development at the hands of the inventors.

table. On the other hand, even in non-drying oils, like olive, which are presumably free from glycerides of the linoleic series, the proportion of olein corresponding to the halogen assimilated, exceeds 100 per cent., a fact which suggests that the methods of operating adopted have not entirely prevented the formation of bromo- or iodo-substitution products, though Mills obtained, with purified triolein, and Hübl with pure oleic acid, results closely in accordance with theory. Hübl's figure for cacao butter indicates that this fat is not approximately pure stearin, as commonly represented. The low figures of both Mills and Hübl for Japan "wax" are remarkable, as also the difference between the absorptions of carnauba and beeswax. Mr. Reginald Moore has obtained figures for the iodine-absorptions of oils which agree closely with those of Hübl, whose process he strongly recommends.

Valenta's Acetic Acid Test.—The behaviour of various fixed oils with glacial acetic acid has been recently investigated by E. Valenta (*Dingl. Polyt. J. cclii.* 296; *Journ. Chem. Soc.* xlvii. 1078). Equal "parts" of the oil and of glacial acetic acid of 1056·2 specific gravity are mixed,* and gradually heated, with continuous shaking, until complete solution takes place, or the acid begins to boil. A thermometer is then immersed in the liquid, the tube allowed to cool slowly, and the temperature recorded at which the liquid becomes turbid. I have tried this test on a number of oils, and find a slight variation in the strength or proportion of the acid employed is not of importance, and that the temperature at which turbidity occurs with any particular specimen is readily observed and fairly constant. Unfortunately my experience is not in accord with that of Valenta as to the turbidity-temperatures of particular oils, a fact that renders it probable that different specimens of the same description of oil give results showing considerable variations. The discordant figures obtained by Valenta and me for palm oil are probably due to the different proportions of free acid in the samples; and the same explanation may account for Valenta's figures for green and yellow olive oil.

The table on next column shows the results both of Valenta and myself.

From an inspection of the table, it would appear that olein is only with difficulty soluble in glacial acetic acid, and that the same is true of stearin. The discrepancy between the figures for the turbidity-temperature of palm oil makes the solubility of palmitin uncertain; but it is evident that the glycerides of fatty acids lower than palmitic (as contained in porpoise oil, butter fat, cocoa-nut oil, laurel oil, nutmeg butter, etc.), dissolve with comparative facility. I have obtained remarkably constant results from several samples of butter, and it appears probable that further experience may prove the method to afford a simple means of distinguishing butter from butterine. The incomplete solubility of rape oil and other oils, from the *cruciferae*, even at the boiling-point of acetic acid, is noteworthy, as are the low figures found for linseed oil, niger-seed oil, and menhaden oil, as compared with those for the non-drying oils.

Valenta has also proposed to employ glacial acetic acid at 50° C. for distinguishing mineral oils from rosin oils, the former being sparingly, and the latter readily, soluble in that reagent.

Determination of Glycerin.—The determination of the glycerin produced by the saponification of fixed oils was, till recently, a very unsatisfactory and uncertain operation, chiefly owing to the loss of

* See. of the sample of oil, previously melted, if necessary, at a gentle heat, and an equal measure of glacial acetic acid are convenient quantities to employ.

glycerin by volatilisation. The problem has, however, been recently solved in a fairly satisfactory manner by the employment of a process originally suggested by Mr. J. A. Wanklyn, further worked out by Mr. W. Fox, and perfected by Benedikt and Zsigmondy (*Chem. Zeit.* ix. 975; *Jour. Soc. Chem. Ind.* iv. 610). The method depends on the saponification of the oil, and oxidation of the resultant glycerin by permanganate in alkaline solution, with formation of oxalic acid, carbon dioxide, and water, in accordance with the following equation—

The excess of permanganate is then destroyed by a sulphite, the liquid filtered from the oxide of manganese, the filtrate acidulated with acetic acid, and precipitated by a calcium salt. The precipitate consists of calcium oxalate mixed with more or less sulphate, silica, etc., and hence cannot be directly weighed. It may either be ignited, and the amount of oxalate previously existing deduced from the volume of standard acid required for the neutralisation of the residue, or the precipitate may be treated with dilute sulphuric acid, and titrated with standard solution of permanganate. A direct titration of the acidulated filtrate from the manganese precipitate, even when the use of an excess of sulphite has been carefully avoided, has been proved by a number of experiments made in my laboratory by Mr. J. C. Belcher, to give results in excess of the truth, apparently in consequence of the formation of a dithionate. When, however, the process is completed in the manner recommended by Benedikt very satisfactory results are obtained. The accuracy of the process has been fully confirmed in my laboratory by experiments on known quantities of oxalic acid and glycerin.

When, however, the method is employed for determining the glycerin produced by the saponification of oils, a serious practical difficulty arises. Ordinary (ethylic) alcohol yields a considerable, though variable, proportion of oxalic acid by oxidation, and if, as recommended by Wanklyn and Fox, alcoholic potash be employed for effecting saponification, it becomes practically impossible to eliminate all trace of alcohol by evaporation without incurring or risking the loss of an appreciable quantity of glycerin. To avoid this difficulty, Benedikt and Zsigmondy employ "pure methyl alcohol." In my experience, the article obtainable under this name in commerce yields a very appreciable quantity of oxalic acid when evaporated with caustic alkali, and the residue oxidised with permanganate. In my laboratory, the preparation of methyl alcohol which will stand this test has proved so troublesome as practically to negative its employment; and hence I have latterly aimed at effecting saponification by aqueous alkali, and thus completely avoiding the source of error in question. Complete saponification in an aqueous liquid is, however, not easy to effect with certainty,* and it was only after numerous failures that I succeeded in hitting on such a mode of procedure as appears to ensure complete saponification with a minimum of manipulation. In my experience, the best results are obtained by placing 5grms. of the

sample of fixed oil in a six-ounce bottle, together with a solution of 2grms. of good caustic potash in 12cc. of water. The bottle is securely closed and heated in a water-oven, or in boiling water, for eight or ten hours, the contents being frequently agitated.† When the product is perfectly homogeneous, and all oily globules have disappeared, the bottle may be opened, and the soap diluted with hot water, when a perfectly clear solution should be obtained, except in the case of sperm oil, waxes, and other bodies yielding insoluble alcohols on saponification. The soap solution is then treated with a moderate excess of acid in the usual way, and the liberated fatty acids separated from the aqueous liquid containing the glycerin, which latter is then ready for oxidation with alkaline permanganate in the manner already described.

The following table gives the percentages of glycerin yielded by the saponification of various fixed oils and fats, as ascertained by the permanganate process. The figures marked with an asterisk were obtained by the use of methyl alcohol, which experiment subsequently showed was not of satisfactory purity. Hence these results are probably somewhat in excess of the truth. The rest of my results are rather below than above the truth, and were obtained by saponification with aqueous potash, while Benedikt and Zsigmondy used methyl alcohol. Fox and Wanklyn recommend ethyl alcohol, but have not published any figures.

It is interesting to compare these figures with those obtained by M. Chevreul, given in his classical *Recherches Chimiques sur Les Corps Gras d'origine animale*, published in 1823. His glycerin was extracted and weighed as such after being purified by

* It is a fact not generally known that the saponification of fats on a larger scale by the "autoclave" process, which consists in heating the substance with water and a base under a pressure of 8 to 12 atmospheres, is often very incomplete. Olein is more difficult to saponify than is stearin or palmitin, and hence, when the product is subjected to pressure, the solid fatty acids are almost free from neutral fats; but the oleic acid is apt to contain a considerable proportion of unaltered glycerides.

† No practical advantage is gained by effecting the saponification under increased pressure in a sealed tube.

alcohol, dried in a vacuum, and the ash left on igniting it deducted from the gross weight found. His results are doubtless low, owing to unavoidable volatilisation during the concentration of the aqueous liquid.

PRODUCTS OF SAPONIFICATION OF ANIMAL FATS—
CHEVREUL.

Mutton	8'00	96'50	30
Butter	11'85	88'50	5'0*
Porpoise Oil ..	11'00	82'20	16'0†

From these tables it appears that the proportions of glycerin yielded by the majority of fixed oils confirm the generally accepted views of their constitution. The case of butter fat is especially interesting, as the results negative the theory of Wanklyn and Fox, that butter contains a notable proportion of *isoglycerides*, and that the butyric acid obtained on saponifying it is really derived from the splitting up of the resultant isoglycerin into a fatty acid and water :

The result yielded by oat-fat, which was prepared in my laboratory by exhausting oat-meal with ether, refutes the statement of König, who could obtain no glycerin by saponifying oat-fat, and but little from linseed oil. The high proportion of glycerin obtained from cocoa-nut oil, fully bears out anticipations founded on the knowledge that it consists largely of glyceryl trilaurate, and contradicts the extraordinary statements of Hammerbocker and Lehmann that cocoa-nut oil consists chiefly of free fatty acids. I propose to consider further the results obtained by Benedikt's process, together with others which have grown out of them, in a future paper.

DISCUSSION.

The CHAIRMAN said that the meeting had listened to Mr. Allen's paper with great interest, and they were all struck by the ingenuity of the appliances exhibited by him for testing the viscosity of oils. He hoped to hear remarks from the various public analysts present on the application of Westphal's hydrostatic balance in the determination of the specific gravity of fats and oils.

Mr. THOMSON said that one disadvantage of taking specific gravities with Sprengel's tubes was that one could not introduce a thermometer into them to ascertain whether the liquid inside had the same temperature as the bath. He had himself obtained good results by using a very simple apparatus, devised, he thought, originally by Prof. Thorp and Mr. Hannay. A piece of glass tubing was drawn out at either end into fine tubes, and in the centre was blown into a sort of elongated bulb. One end was then bent upwards until that which had resembled a pipette assumed the shape of a U-tube. The same end was again bent outwards above the level of the bulb to

form a sort of spout. The other end, which was left straight, was then marked with a scratch a little below the level of the outward bend on the crooked tube. The whole was then heated in a paraffin bath, in which it was immersed, to within a quarter-of-an-inch of the top. In the same or a similar bath was a test tube containing the fat or oil, the specific gravity of which was to be determined. When the required temperature was reached, the operator took out the U-tube, and drew in through the spout sufficient oil from the test tube to fill the apparatus up to the mark. Further entrance of oil was then stopped, closing the orifice with the finger. The whole was then carefully wiped and weighed. As regarded Westphal's balance, it certainly gave equally accurate results as the specific gravity bottle, and with less trouble. As to Fox and Wanklyn's method of glycerin estimation, he would be glad to know if the author took into account any free acid which might exist in the samples which he examined. Perhaps he would also state whether he found any difficulty in cleaning the paddles of his viscosity-apparatus.

Mr. J. CARTER BELL said that he had used an apparatus for some years, similar to that exhibited by the author, for taking specific gravities of butter and other fats. He was not sure that the latest modification made by Mr. Allen was an improvement, as the agitation of the water would cause the tube to leave the perpendicular. With paraffin one had a constant level, which was not the case with water. Would not the steam also affect the balance?

Mr. ESTCOURT was sorry that the title of Mr. Allen's paper had given no idea that he would enter so fully into the question of taking specific gravities at high temperatures with the Westphal balance, for he (Mr. Estcourt) could have shown the meeting the instrument originally made for him by Westphal, with the bath he had himself devised some nine years back, for taking the specific gravities of butter at or near 212° F. (see *Chemical News*, vol. xxxiv. p. 254; *Ib.* vol. xxxviii. p. 267). Since that time he had used the balance largely for milk, spirits, and other liquids; and for butter he knew no instrument that could replace it. He had then tried it for the thicker or viscous oils with equally good results. It was at his suggestion that the author had adopted the same system; and much credit was due to him for the way in which he had extended its use. As regarded the use of water as the immediate source of heat, it was no special improvement, though the device of the indiarubber ring certainly prevented any steam reaching the beam of the balance.

Mr. GRIMSHAW said that methyl alcohol was now being produced in an almost perfect state of purity. He would refer the author to Mr. Fawsitt's paper, read before the Glasgow Section (see this *Journal*, vol. iv. p. 319).

Mr. C. RAWSON (of Bradford) suggested that the difficulty experienced in accurately estimating glycerine by converting it into oxalic acid, would probably be overcome by adding a large amount of water, and then boiling the solution of soap and glycerine down to a small bulk.

Mr. ALLEN said that the only essential difference between the apparatus used by him, and that devised by Mr. Estcourt, for determining the densities of fats at the boiling-point of water, was the omission by him of the intermediate bath of paraffin. He had not the least objection to Mr. Estcourt's contrivance, except that he thought it unnecessary. He was not surprised to learn that Mr. Bell had habitually used the hydrostatic balance for the general purposes of the laboratory, as it was contrived by Westphal with that object; but he hoped to see the instrument more

* Equal to 2'83% of butyric acid.

† Equal to 9'63% of valeric acid.

frequently employed in future than had been the case hitherto.

As to the impurity in commercial methyl alcohol, which interfered with its employment for the determination of glycerine, he might point out that in an ordinary estimation, about 30cc.—say 25grms.—of the reagent was employed. If this contained even 1 per cent. (= 0.25grms.) of an impurity—which he presumed to be acetone or an allied body, which would yield oxalic acid by the subsequent treatment—it would be fatal to the accuracy of the process; as the amount of glycerin to be determined did not exceed 0.5grm. As to ethyl alcohol, that itself yielded oxalic acid by oxidation; and test experiments, in which alcohol was evaporated with caustic alkali, and the residue oxidised with permanganate, showed that it was not possible in practice to avoid the formation of oxalic acid without risking the loss of glycerine. In the saponification with aqueous alkali, evaporation was entirely dispensed with; but it would undoubtedly be a great advantage if methyl alcohol fit for the purpose could be procured, or prepared with reasonable facility.

It might interest the meeting to know that M. Chevreul, who had recently celebrated his hundredth birthday, in a reply to a communication from Mr Allen, stated his intention to revise and complete his researches on fats, after which he proposed to devote his spare time to the neglected correspondence of the last fifty to sixty years.

Meeting held January 5, 1886.

MR. LEVINSTEIN IN THE CHAIR.

ON THE EXAMINATION AND ANALYSIS OF CERTAIN MATERIALS USED IN DYEING AND CALICO PRINTING.

BY ROWLAND WILLIAMS, F.C.S.

THE subject which I am about to bring before you this evening is, I think, one of considerable importance to a section of a Society like ours, composed as it is of scientific and practical chemists, bleachers, dyers, calico-printers, and other persons engaged in, or more or less connected with, chemistry in its various applications.

The comparatively short space of time at my disposal will not permit me to cover so much ground as I should like to do, and I shall, therefore, confine myself to a few of the more important substances employed in dyeing and calico-printing.

I propose to give my experience of some of the methods generally employed in the examination of these dyewares, and at the same time to suggest occasional modifications, which I have found useful, and which may, perhaps, also be of value to others engaged in the testing of similar materials.

First, I will call your attention to that very important substance, *Alizarin*. Artificial alizarin is generally met with in commerce as a paste, containing 10, 15, or 20 per cent. solid matter, which, in many cases, is not pure alizarin, but a mixture of that substance with various proportions of anthra-purpurin, flavo-purpurin, etc.

With alumina mordants, pure alizarin yields red shades inclining to blue, whilst the presence of anthra-purpurin and flavo-purpurin modifies the shade considerably, the former giving a purer red, whilst the latter tends to produce a yellowish tint. Perhaps the

most satisfactory method for the examination of alizarin is to make a practical test in dyeing, or printing, or both, and observe the shade produced, after steaming and soaping.

In many cases it is useful to take the specific gravity, and to estimate the total solid matter, and afterwards to ignite the latter, when only a slight residue should remain, if the alizarin be fairly pure. In good makes of alizarin I have generally found the specific gravity and total solid matter to have a close connection with the shades produced in dyeing and printing.

In badly prepared alizarin, minute reddish brown specks are sometimes found, and a careful search should be instituted for these, as they are liable to cause uneven, freckly shades, especially when the alizarin is used for printing.

Starches should always be specially examined for grit, by mixing into a thin paste with cold water on a porcelain slab, and feeling very carefully with a spatula, or with the finger, for any traces of gritty matter which may be present. I may say, in passing, that freedom from grit of the various materials employed in calico-printing cannot be too highly insisted upon. If grit be present in the starches and other substances used in making colours, it is certain to be found in the colours when ready for printing, as no amount of straining—even through the finest straining cloth—will entirely remove this finely divided gritty matter, which is the cause of so much damaged work. A paste should also be prepared by boiling a portion of the sample, and compared in respect to colour, consistency, etc., with a paste made from a standard sample of starch. Up to the present time no very accurate method has, I believe, been devised for determining the consistency or body of starch paste. The plan, which is sometimes adopted, of noting the weight which a paste will bear without breaking, is not satisfactory; and perhaps as good a way as any to form a judgment on the consistency of starch paste is by careful pressure with the finger. Moisture and ash should be determined in the usual manner, and a microscopical examination of the sample should also be made.

Bichromate of potash is largely used in dyeing and calico-printing for the production of chrome yellows, and for other purposes. Owing to the comparatively high price of potassium bichromate, attempts have, for some time past, been made to replace it by the cheaper soda salt. The desired result has at length been attained; and bichromate of soda is now employed in large quantities by dyers and calico-printers, instead of the corresponding potassium salt. It has been asserted that potassium bichromate produces brighter yellows than sodium bichromate, but my experience does not confirm this statement. I have here several printed samples of various designs, certain parts of which have been prepared with acetate of lead, and then raised by passing through baths of bichromate of soda and potash of equal strength. On examination of these patterns, I think you will admit that those raised by means of sodium bichromate are equal in every respect to those in which potassium bichromate has been employed. Commercial bichromate of soda is made so as to contain about the same percentage of chromic acid (the valuable constituent) as bichromate of potash, and as the former costs a penny per lb. less than the latter, it will at once be seen that an enormous saving must result from the employment of the soda compound. Bichromate of soda possesses the additional advantage over bichromate of potash, that it dissolves much more readily in water, often saving valuable time when work is urgent. The estimation of the chromic acid in bichromates is best performed by a known

excess of pure ferrous sulphate or ferrous ammonium sulphate to a fairly strong solution of the sample in water acidified with sulphuric acid. The excess of iron existing as protoxide is then determined by means of standard bichromate solution.

Alum and Sulphate of Alumina.—It is advisable to test for free acid in these substances, and this is best done by means of a dilute solution of the colour known as Congo red, which is changed to a beautiful blue by the slightest trace of free acid, whilst it is not affected by alumina itself, provided the Congo red solution be sufficiently dilute. The amount of free acid present in sulphate of alumina is usually determined by leaving a weighed quantity of the finely powdered sample in contact with strong alcohol overnight. The alcohol is then filtered off, and the sulphate of alumina washed several times with strong alcohol. The alcoholic filtrate is then diluted with water, and concentrated on the water-bath until the odour of the alcohol has entirely disappeared, and the residue is of syrupy consistency. This is then treated with absolute alcohol, which throws out of solution most of the alumina which may have been dissolved during the earlier stages of the process. The liquid is filtered through a small filter, which is afterwards washed with absolute alcohol. The alcoholic filtrate is then diluted with water, and titrated with standard caustic soda, using phenolphthalein as indicator. I have endeavoured to devise a colorimetric process for the direct estimation of the free acid in alum cake and in similar substances, by comparing the depth of colour produced by adding Congo red solution to an aqueous solution of the sample, with that obtained in a similar manner from a very dilute acid liquid of known strength. So far, however, my results have not been very satisfactory; but I hope shortly to overcome the difficulties connected with the process, which would, if reliable, be very convenient for those who have to make a large number of analyses of this description.

Red Liquor should be submitted to a practical test by mordanting a piece of cloth with the sample, and, after ageing, etc., dyeing up with alizarin. In addition, it is often necessary to determine the amounts of acetic acid and alumina present. The acetic acid is best estimated by distillation with pure phosphoric acid, and titration of the acid distillate with standard caustic soda solution. With regard to the estimation of the alumina, it may, perhaps, seem almost unnecessary to warn chemists of the inaccuracy of the results which would be obtained by precipitating the alumina directly from the diluted red liquor, and yet I have known serious errors to arise from this cause. Usually the results obtained by direct precipitation are too low, owing to the presence of organic matter, but I have occasionally met with samples which, when precipitated directly, have indicated about 1 per cent. of alumina above the amount actually present. The method which I have found to give the best results is to evaporate a weighed quantity of the red liquor to dryness in a platinum vessel, ignite the residue, dissolve in hydrochloric acid, filter, and precipitate the alumina in the filtrate with a slight excess of ammonia. The alumina precipitate is then filtered off, washed, dried, and ignited in the usual manner. It is not necessary to ignite the residue from the evaporated red liquor to perfect whiteness; in fact, I find it a disadvantage to do so, as strongly ignited alumina is only soluble in hydrochloric acid with difficulty, thus occasioning loss of time. I append the following results, which were obtained in my laboratory by determining the alumina in three samples of red liquor, (1) by direct precipitation, (2) by precipitation after partial ignition, (3) by precipitation after complete ignition.

Sample No.	Direct.	Alumina.—Per Cent.		
		Partial.	Complete.	Complete.
Sample No. 1	2.19	2.41	2.40	2.40
Sample No. 2	3.01	3.18	3.20	3.20
Sample No. 3	3.31	3.42	3.45	3.45

From the above it will be seen that practically the same results were obtained whether the residue was only partially or whether it was completely ignited, but that the figures found by direct precipitation vary considerably from the actual percentages of alumina present.

Bleaching Powder.—In connection with the testing of this substance, I may mention a slight modification of my own of the ordinary process for the estimation of available chlorine, which has proved very useful when I have had several samples of bleaching powder in my laboratory at the same time. As is well known, the usual plan is to weigh out 10grms. of the bleaching powder, grind this in a mortar with successive quantities of water, and finally make up to a litre. Measured quantities of this are then taken for titration, usually with sodium arsenite, or ferrous sulphate solution, in order to estimate its oxidising power. My method of procedure is to weigh out two small quantities of each sample, say 5 or 6 grains, from a stoppered weighing tube, into flasks of 10 or 12oz. capacity, treat each with about 1000 grains of water, and then shake each flask thoroughly. I then add an excess of decinormal sodium arsenite solution to each, and after mixing well I add a little starch solution, and run in decinormal iodine solution until the blue colour appears. The calculations are then easily made. I find this modified method gives results practically identical with those obtained by the usual process, and it possesses the decided advantage that duplicate estimations can be made by it in as short a time as is required for a single determination by the ordinary process.

Glycerine.—In addition to the tests mentioned in various works on this subject, I would also suggest that of ascertaining the amount of arsenic which the sample will dissolve, as this is one of the principal uses of glycerine in many print works. The experiment may be made by heating together for some time a weighed quantity of glycerine and a known excess of arsenious acid. The solution is then diluted with water, filtered through a tared filter, the residue thoroughly washed, dried, and then weighed. The quantity of arsenic dissolved by the glycerine is then readily ascertained by subtracting the weight of the residue from the amount of arsenious acid originally taken. If desired, the arsenic in solution may also be estimated in the filtrate by means of standard iodine solution. Good glycerine should dissolve about 6lb. arsenic to the gallon.

Oleine.—The substance which is sold to dyers and printers as oleine, is usually a compound of sulpho-ricinoleic acid, with soda, potash, or ammonia. The best process for the estimation of the fatty acids is that mentioned in Allen's "Organic Analysis," which consists in weighing out 10grms. of the sample, and heating with 25grms. white wax and 75cc. of a cold saturated solution of common salt, in which the liberated fatty acids are practically insoluble. When cold, the resultant cake should be dried as completely as possible with a little bibulous paper, and then heated gently until every trace of water is dissipated. The final gentle heating of the fatty acids should never be omitted, or the results will certainly be too high, owing to the fatty mass occluding a certain amount of water. I find that what may be termed the "ether process" does not yield trustworthy results, owing to the ethereal extract being contaminated with water and with mineral matter (usually sulphate of soda), which have not been completely removed in the earlier stages of the analysis. The "ether process"

sometimes gives results two or three per cent. higher than the "salting-out process." The following results were obtained from a sample of oleine, which had been carefully prepared in my laboratory so as to contain 50 per cent fatty acids:—

Fatty acids	Ether process.	Salting-out process.
	52.82.	50.12.

These figures show very clearly that much more accurate results are obtainable by the "salting-out process" than by the "ether process."

Tartar Emetic.—The most accurate method for the estimation of antimony in tartar emetic is by precipitation as sulphide from an acid solution by means of sulphuretted hydrogen gas. Quite satisfactory results may, however, be obtained by the ordinary process, in which the oxidation of the antimonious acid into antimonie acid is effected by iodine in alkaline solution. Whilst on the subject of tartar emetic I should like to say a few words about its substitute—viz., antimony potassium oxalate. As is well known, there is considerable difference of opinion among the various authorities with regard to the respective values of the tartrate and oxalate of antimony and potassium. Now, as the tartrate usually contains at least half as much antimony again as the oxalate, one would naturally expect the former to give correspondingly better results than the latter, but this is not the case. On the contrary, I have found, from experiments made in my laboratory, that in piece and yarn dyeing better results are in many cases obtained with the oxalate than with the tartrate, even when equal weights of each are employed, although the former only contains about two-thirds the quantity of antimony present in the latter. This peculiar result is, without doubt, as Dr. Witt has suggested, due to the fact that the oxalate dissociates more easily than the tartrate, and, consequently, fixes the tannic acid more readily and more completely in the fibre. In order to prove to you the more rapid dissociation of the oxalate of antimony and potassium, I have placed in one of these beakers a solution of that compound, and in the other a solution of tartar emetic, both of the same strength—viz., 10grms. per litre. On addition of equal quantities of this tannic acid solution to each beaker, you will observe that in the case of the oxalate the precipitate appears immediately, and soon settles to the bottom, whilst in the tartar emetic the precipitate takes a considerably longer time to form. I have here samples of cloth and yarn which have been steeped in tannic acid solution, and then passed through baths containing respectively 5, 7½, 10, and 20grms. per litre of the tartrate and oxalate. The cloth was then dyed up with methyl green, one part of the yarn with methylene blue, and the other part with malachite green. In the case of the cloth comparatively little difference can be detected between the respective pieces, but the results obtained with the yarn, especially that dyed with methylene blue, are very striking. It will be seen on examination of these dyed samples that in every case, with the exception of the strongest (20grms. per litre) bath, the oxalate has given the better results of the two. This latter result confirms M. Nölting's statement that "oxalate baths too concentrated do not act so well as more dilute baths." The best result was obtained by using an oxalate bath containing 10grms. per litre, this being found to act more satisfactorily even than the tartrate bath (20grms. per litre), notwithstanding the fact that the latter contained three times as much antimony as the former. I have not had any practical experience in the use of the oxalate for fixing complicated printed patterns, but I am informed by the manager of one of the largest printworks in this

neighbourhood, that, for every style, it may be substituted for tartar emetic with perfectly satisfactory results.

DISCUSSION.

The CHAIRMAN said that the author appeared to him to be too sure that antimony oxalate did replace tartar emetic weight for weight. Had he read an account of the recent investigations of Drs. Lauber and Boetsch, which unfortunately added to the already too conflicting evidence on the subject? Without wishing to forestall the report of the Committee formed to investigate the comparative values of these substances, he might go so far as to say that antimony oxalate did not appear in all cases to be an economical substitute for tartar emetic, or even universally applicable. The use of Congo red as an indicator of acidity had already been alluded to some months since in some of the German papers.

Mr. A. H. ALLEN said one statement of Mr. Williams, in connection with the assay of "soluble oil," appeared to him a remarkable one, as it practically amounted to an experience that sodium sulphate was withdrawn from an aqueous solution by agitation with ether. He would ask whether the usual precaution was taken of agitating the ethereal liquid with fresh water after separating it from the aqueous layer. Some commercial ether contained from 12 to 15 per cent. of alcohol, the presence of which gave it a tendency to dissolve some saline matter, though sodium sulphate would not be among these. The alcohol could be removed by several agitations with water, and the ether dried by digestion over sodium.

Mr. WATSON SMITH, in reference to the question of impure alizarin pastes, said that modern Turkey-red dyers and printers preferred pastes containing *pure* flavo-, or anthra-purpurin, which they could mix themselves if necessary. Such pastes could now be readily obtained, and any desired shade could be had by judicious admixture of the pure ingredients. He had tried the "Congo red" test and had found it answer well. In Spence's alum works they regularly used a test based on the decolorisation of yellow solution of ferric acetate by solution of alum containing free acid. This gave good results by daylight, but by gas-light he should prefer the "Congo red."

He considered Mr. W. B. Hart's method of testing tartar emetic (see Journal, vol. iii. p. 294) to be the best for speed and accuracy. Mr. Tyrer, whose firm manufactured this article, had also reported very favourably of it.

Mr. THOMPSON had not been so successful as the previous speaker with the Congo red test. Having ground up some potash alum and washed it thoroughly with alcohol, he dissolved it in water and applied the test, when the solution became blue. Perhaps he had failed to eliminate every trace of free acid, for certainly a very small quantity of acid sufficed to render the solution deep blue. Perhaps the author would tell them whether he had been able to prepare a sample so free from acid as not to affect the red colour. As regards the comparative samples of dyed yarn exhibited, those treated with antimony oxalate were certainly superior. Perhaps the Chairman, who had taken a special interest in the question, would tell them how there could be any longer doubt as to which salt of antimony was the more economical mordant.

Mr. C. RAWSON said that he had made comparative tests both in the laboratory and the dyehouse on the use of sodium and potassium bichromates as mordants. He had found that in those cases of wool-dyeing where the mordant was applied previous to the dye-stuff, pure sodium bichromate gave equally

good results as the potassium salt. But in the dyeing of *fast browns* by the so-called "saddening method" (where the mordant was applied after dyeing) potassium bichromate invariably gave better results. With *sodium* bichromate as the mordant, a greater weight of the dyewoods was required to produce a given shade than when *potassium* bichromate was used as the "saddening" agent. Although the active principle in each salt was the same—viz., chromic acid—it might be that the nature of the *bases* played an important part in the "saddening" process.

Mr. HEYWOOD had also found sodium bichromate not quite so satisfactory as bichromate of potassium for dyeing "catechu browns," but it was a long while since, and probably the salt was impure.

Mr. POTTER, as the original maker of bichromate of soda in this country, was glad to hear, from the remarks of the various speakers, that the prejudice against use of this salt was now dying out.

Mr. WILLIAMS: In reply to Mr. Allen's question as to the reason why the ethereal extract might not be washed with water in the estimation of fatty acids in oleine by the "ether process," I may point out that, inasmuch as sulphoricinoleic and other sulphonic acids contained in oleine are soluble in water to a considerable extent, the results would be much below the truth if this plan were adopted. To prove that such is the case, I may mention an experiment which I made with the sample of oleine previously referred to. When the ethereal extract was not washed, I obtained nearly 53 per cent. fatty acids instead of 50 per cent. actually present; but when the ethereal solution was washed two or three times with water, I only obtained about 45 per cent. fatty acids.

Mr. Watson Smith is correct in asserting that commercial alizarin may be obtained almost pure *if desired*. Pure alizarin, however, as I stated at the commencement of my paper, yields reds inclining to blue, whereas it is sometimes necessary to produce pure reds, and at other times reds with a yellowish east. In order to meet these requirements for full reds, a certain proportion of anthra-purpurin is mixed with the alizarin of commerce, whilst for yellow shades of red a little flavo-purpurin is introduced.

With reference to the ferric acetate test for free acid in alum, I have often tried it, but have generally found it unsatisfactory, and I can strongly recommend the Congo-red test in preference. I have also tried Mr. W. B. Hart's modified method for the estimation of antimony tartar emetic, but fail to find it any advantage over the ordinary process.

In reply to Mr. Thomson, I have no doubt that he did not wash away every trace of free acid from the alum with which he experimented, otherwise he would have obtained no blue colour with Congo-red solution, which, as I stated before, if sufficiently dilute, has no action on alum itself.

The results of my experiments confirm Mr. Heywood's experience in the use of antimony potassium oxalate, which he finds to give better results than tartar emetic in uni-colour dyeing. With regard to its applicability for fixing complicated printed patterns, the manager of a very large printworks near Manchester, where a great variety of work is done, informed me a few days ago that they had been using the oxalate for the last three months, and that it gave every satisfaction.

As Mr. Allen has suggested, the exceedingly contradictory results on this point which have been obtained by various persons, may possibly be accounted for by the samples with which they experimented having been largely contaminated with sulphate of potash or with other adulterants.

Meeting held Tuesday, 2nd February.

MR. WATSON SMITH IN THE CHAIR.

ON SACCHARINE—A NEW SWEETENING AGENT DERIVED FROM COAL TAR.

BY IVAN LEVINSTEIN.

I AM desirous of bringing under your notice this evening a substance which, known for the last few years only to specialists as a chemical curiosity* on account of the difficulty of its production, is likely, in consequence of further improvements by its discoverer in the process of manufacture, to enter the market as a commercial product.

Modern chemistry has achieved a new triumph—one, indeed, the commercial importance of which cannot yet be fully realised. From the black viscous liquid, gas tar, has been prepared, an article which seems likely to enter into daily consumption. We have scarcely as yet become fully familiar with the ever-increasing number of coal-tar dyes, with the production of aromatic substances and those possessing powerful antiseptic and medicinal properties from the same prolific source, when the fresh and startling announcement is made that, by a novel treatment of one of the components of coal tar, a compound may be obtained possessing very similar sweetening properties—but in a far more intense degree—to the best cane or beetroot sugar. The commercial name given to this singular substance by its discoverer, C. Fahlberg, a German chemist residing in the United States, is "saccharine." It is not my intention this evening to diverge into any speculations as to the probable economic effects of this wonderful discovery, great as the temptation may be; I shall confine myself to a brief description of the mode of production, and the general and physiological properties of saccharine, and I will also give you an opportunity of inspecting the substance itself and some of its compounds. The chemical name of saccharine is benzoyl sulphonic imide, and it may be expressed by the chemical formula

In order to obtain saccharine, Fahlberg† commences with toluene, a hydrocarbon present, as you are probably all aware, in coal tar. This toluene C_6H_5 (CH_3) he converts into its two monosulphonic acids

and transforms these by treating them with phosphorus-pentachloride (PCl_5) into the corresponding toluene-sulphonic chlorides

Of these two toluene-sulphonic chlorides—viz., the para and the ortho—only the ortho compound, which is liquid (the other being solid), is suitable for the production of saccharine. By the introduction of the amido group of ammonia, this ortho-toluene-sulphonic chloride is then converted into ortho-toluene-sulphanide

which finally yields, by oxidation, the benzoyl sulphonic imide or saccharine.

* American Chemical Journal, vol. 1, page 170; and vol. 2, page 181, and fol. I, page 425.

† Eng. Pat. 6626, June 1, 1885; specification of James Yate Johnson. This Journal, iv. p. 608.

Saccharine presents the appearance of a white powder, and crystallises from its aqueous solution in thick short prisms, which are with difficulty soluble in cold water, but more easily in warm. Alcohol,* ether, glucose, glycerol, etc., are good solvents of saccharine. It melts at 200° C., with partial decomposition; its taste in diluted solutions is intensely sweet, so much so that one part will give a very sweet taste to 10,000 parts of water. Saccharine forms salts, all of which possess a powerful saccharine taste; it is endowed with moderately strong antiseptic properties, and is not decomposed in the human system, but eliminated from the body without undergoing any change. It is about 230 times sweeter than the best cane or beetroot sugar. According to Dr. Stutzer, of Bonn, who has carefully investigated the physiological properties of this substance, saccharine, taken into the stomach in the quantities in which it has to be added to food as a sweetening material, has no injurious effect whatever on the human system. Stutzer has given to dogs about 5grms. a-day, without observing any ill effects in them, and when we consider that 5grms. are equal in sweetening power to rather more than 2½lb. of sugar—a quantity far larger than anyone would like to consume in a day—his views seem amply corroborated by this fact alone; but, in addition to this, patients suffering from diabetes have now been treated for several months in one of the principal hospitals in Berlin, as I am informed, without their feeling the least inconvenience by its use. Physicians must be glad to find in saccharine a substance by means of which diabetic persons may enjoy food which has hitherto not been admissible in their case. Saccharine does not belong to the class of carbohydrates, and does not possess nutritive properties. The use of saccharine will, therefore, as indicated by its properties, be not merely as a probable substitute for sugar, but it may even be applied to medicinal purposes where sugar is not permissible. The inventor was fully aware that in order to supply a perfect substitute for cane or beetroot sugar, something else—viz., a similar substance—was needed for confectionery and similar purposes, besides sweetening properties, and he has also endeavoured to solve this problem. Dr. Fahlberg combines glucose with starch sugar, a substance very similar to cane or beetroot sugar, as you know, but inferior to these in sweetening properties, with saccharine, and thus obtains a compound which he calls “dextro-saccharine,” which, as far as the taste is concerned, is scarcely distinguishable from the best sugar. The quantity of “saccharine” used is in the proportion of one part to from 1000 to 2000 parts of glucose. Now, if we look at the price of saccharine, which is, I believe, at present about 50s. a-pound, we shall find that even at this price such a mixture would be very considerably cheaper than real sugar, but we must bear in mind the fact that there is great likelihood of the process of manufacture of saccharine being considerably cheapened; the expensive phosphorus-pentachloride may probably be replaced by a cheaper compound, etc.

It will then be evident, from what you have heard, not only that “saccharine” is a most interesting compound, but that it may also be destined to become an article of primary commercial importance. I must leave to the future to decide as to the revolutions it may bring about in the coal-tar industry, in the cultivation of the soil now devoted to growing canes or beets, and in the sugar industry generally, and other industries connected with it; but as great

and important commercial interests are in question, it is highly advisable to look well into this matter, and not to allow our foreign competitors in this and other markets to secure exclusively for themselves the benefit which this discovery may confer. I have here for your inspection a specimen of pure crystallised “saccharine,” and also small balls made from starch, to which has been added 0.05 per cent. of saccharine, of which one is sufficient to impart a very sweet taste, very similar to that of the best sugar, to a large cup of black coffee. Further, some liquors sweetened with “saccharine,” some lozenges made from “dextro-saccharine,” and also some raspberry syrup sweetened with saccharine; and finally, a small bottle of quinine, the bitter taste of which has been disguised by the addition of a small quantity of “saccharine.” These samples will give you an idea of the various and manifold uses to which saccharine may be put, and which may result in an enormous consumption of the article.

DISCUSSION.

The CHAIRMAN said it might be well to distinguish between the sugar compound *saccharin* and the benzoyl-sulphonic imide by adding the final *e*, and spelling the latter *saccharine*. It was unfortunate that practically the same names were applied to such chemically different substances. “Saccharine” might prove serviceable for sweetening fruit preserves, which might thus practically consist of pure fruit, the amount of saccharine required being very small. Whether the antiseptic power of this compound would prevent the inroads of mould in preserves thus sweetened, remains still a matter for experiment. His friend, Dr. Fahlberg, had been a member of the Society of Chemical Industry from the outset, and his name would be remembered in connection with a remarkable process for the removal of iron from solutions of alumina by means of plumbic dioxide, afterwards more cheaply replaced by “Weldon-mud,” by Spence and Kynaston (this Journal, vol. i. 275).

IVAN LEVINSTEIN IN THE CHAIR.

CHINA GRASS OR RHEA FIBRE.

BY A. SANSONE,

Director of the Manchester Technical School of Dyeing.

HAVING watched very carefully all that has been done in the last few years for the advancement of the study of textile materials, I have come to the conclusion that there is a brilliant future in store for the fibres derived from some of the varieties of the *Urtica* family, and my conviction goes so far on this point as to foresee at no very distant future a new and very important branch of textile industry.

I should like to mention here the valuable book published by Dr. Forbes Royle in 1855 on the “Fibrous Plants of India,” because its study may be useful to those who have invented, or believe they have invented, new methods for the treatment of fibres.

Before describing the processes which have been employed successfully for the extraction of the fibre, it will be necessary to say a few words about the plants themselves, in order to be able to understand the difficulties which had, and have still to a certain extent, to be overcome.

The fibre is found in the bark of the stems, and these reach a height of 3½ to 5½ feet, and under favourable circumstances even more. The size of the

* The solubility of saccharine in ether might probably be useful in detecting its presence when mixed with sugar.

stems varies considerably in thickness, being sometimes half-an-inch, and sometimes even more. When the stems are freshly cut, the bark can be very easily peeled off by hand, and in this case the bark or ribbon contains practically the whole amount of fibre; but if the stems have been standing for some time, or are half dry, or in some cases, as in sunny days, have been cut in the afternoon instead of the morning, then the bark cannot be removed without a certain amount of fibre being lost by adhering to the woody stem which forms the interior.

As well known, China grass of commerce is the product obtained from the stems principally of the *Urtica nivea*, the bark having been first of all stripped off by hand from the stem, and then the raw fibre liberated from the skin and mucilage by scraping with a knife. This product has been used in England for the last forty or fifty years, and since it has been employed for a great variety of purposes, and has been bleached, dyed, and printed without any difficulty; this proves that the separation of the gum from the fibre has been accomplished long ago by well-known methods, employing chemicals of every-day use in the bleach and dyeworks. It is well to bear this in mind when we consider that several processes have been patented in the last few years, in the majority of which it is proposed to employ such simple materials as alkalis and acids, which, so long as there has been any textile industry, have in one form or another always been used.

The methods of treating the stems are twofold, those dealing with the dry and those dealing with the green stems. Several machines have been constructed for treating the dry stems, some of which may be found of utility. There is, however, always a certain amount of loss, and, in many cases, if the woody portion, as often happens in thick stems, is very hard, then the fibre will be cut up or injured; the stems, moreover, must be very dry before they can be effectually treated. But the great difficulty connected with the treatment of the dry stems is to obtain them dry, since in some countries, especially India, the best crops are obtained in the rainy seasons, when it is impossible to dry them. Moreover, the partially dried stems soon begin to ferment, and the fibre is then completely spoilt.

For this reason the Indian Government, in offering prizes for machines for the extraction of the fibre, insists on a construction suitable for dealing with the green stems.

For the above treatment two methods exist, and I am acquainted with both of them; one involves the employment of the Smith's or Death & Ellwood machine, the other two distinct operations the Favier-Frémy methods.

I have been making for the last six or seven months experiments on green stems, which have been kindly supplied on two occasions to me by Professor Thisleton Dyer, the Director of the Kew Botanical Gardens, and of dry stems grown on the Continent, of which I have had ample supply for experimental purposes. I have come to the conclusion that the methods of treatment must be modified according to local circumstances with respect to climate, water, labour, means of transport, etc., and that one method which will be found to answer under one set of conditions will not necessarily hold good under other conditions.

In my opinion, if the fibre of these nettles is to be employed at all, it must be produced so as to be as cheap, and, in fact, cheaper than cotton, and consequently the methods of treatment must be as inexpensive as possible. The simplest method of treatment, following the long experience of the Chinese and other Eastern nations, would be simply

to peel off the bark from the green stems by hand as soon as they are cut, and then dry the bark. This latter could then be shipped to this country for treatment by a chemical process for the extraction of the fibre,—this is, in fact, already done; the only change that could be introduced being the employment of a machine for the stripping off or decortication of the stems—without, however, attempting to extract the fibre at the same time. Machines could be easily devised for this purpose. The difficulty in the treatment of stems freshly cut is that they must be stripped off immediately, and this done by hand would require for large plantations an enormous number of women or children. The difficulty of obtaining sufficient manual labour would be to a certain extent got over by the employment of machines, but a large number of these machines would also be required, and this of course means considerable outlay. I have been therefore considering if something could be devised which would allow of the treatment of the stems at any time of the year and not only at the period of the crops. The simple method I propose I have been led to by considering the results of many experiments, both on green and dry stems. The method is a very simple one, and does not require any expensive plant or apparatus. The method is the following:—

The stems, either green, half dry, or even dry, are boiled in a solution containing carbonated or caustic alkalis. If the stems are green, five to ten minutes' treatment is sufficient, and the bark can then be peeled off without difficulty and without leaving any fibre attached to the wood.

If the stems are half dry they require longer boiling (say 15 minutes), whilst completely dry they require from 20 to 25 minutes. In all cases the bark can be readily peeled off, and could be dried, or washed and dried, and then packed in bales for export. It must be observed that the boiling can be done in an ordinary open boiler of small size, and that if the stems are dry they can even be treated under pressure. It may be asked, What advantage is there in thus boiling the stems? The advantages are as follows:—Firstly, the stems can be treated all the year round in localities where it is not difficult to dry them. They can be kept in store by simple and inexpensive means, and treated when most convenient, since one ordinary open boiler heated over a free fire can be used for treating large quantities. The stems are to be quite immersed during the boiling. They are afterwards removed for stripping, and other stems are then immersed in the same water, which could be kept meanwhile boiling, and only being changed occasionally, and replenished from time to time with more alkaline lye. The woody portion of the stems furnishing very good fuel, it could be employed for heating the boiler, and the ashes would furnish the requisite alkali, since it has been found by analysis that these ashes are very rich in potash and soda. This system of treatment would be especially valuable for small farmers, who would then employ the time they do not spend in the fields for the decortication of these stems. Secondly, when stripping off bark from the green stems, since they are very liable to ferment (even if dry) during a long sea voyage, when exposed to moisture, a boiling in soda is sometimes found necessary before exportation. The work thus done is by no means lost, for by this boiling a certain amount of gum can be removed, along with part of the skin and other impurities, if after boiling and stripping the ribbons be washed with cold water before drying. The boiling of the stems with alkalis is not a new idea, for it is mentioned in Dr. Royle's work, p. 346 (Wright & Co.'s Patent, 1849). However, I think the idea in the form I give it is new. Some of the

specimens I exhibit to-night have been produced in the laboratory of the School of Dyeing; dry stems of several months' standing have been boiled with caustic soda under pressure in a mason's kier. I have frequently treated varying quantities of these stems (once over 2 kilos.), and in all cases after sufficient boiling the bark could be peeled off with the greatest ease, even when thoroughly cold, and the very day after they had been boiled. There would be no difficulty, even in this case, in peeling by machinery. Another advantage in this treatment will appear shortly. In countries like India, where the stems cannot be dried, the method referred to may not have the same importance as in countries where it cannot be carried out, and I have tried to devise means by which this difficulty could be overcome. It is well known that the stems of these nettles are very liable to mould, but it is equally well known that this evil can be prevented by the use of suitable antiseptics, such as sulphurous acid, sulphites, or bisulphites.

The method I would propose for employment in India and in other countries in the rainy season, would be simply to place the stems in large pits or cisterns, with a solution of sulphurous acid or bisulphites, and keep them there until they can be worked by whatever process.

Green stems left in bisulphite of soda solution last summer for several weeks were found quite fresh, and were then treated without difficulty. I do not consider that the heat in India would prevent the sulphurous acid or bisulphite solution from preventing the fermentation, or rather the putrefaction, of these stems, by constructing underground pits or cisterns and covering them with light wooden sheds. The employment of sulphurous acid and bisulphites for this purpose is, I believe, a novel one, and so I think I may claim the credit of suggesting it. It has, moreover, the additional advantage that it bleaches the fibre to a certain extent, for I have been able to obtain a white fibre much more readily than from stems or bark treated differently. I have, in fact, devised and successfully carried out a method for the ungumming and bleaching of the fibre from the stems of the nettles by the aid of sulphurous acid or bisulphites, in conjunction with alkaline treatment. In doing this I do not so much desire to claim any credit for the discovery, as to prevent others from patenting a process which I would more willingly contribute for the public benefit.

In many of the methods employed for the extraction of the fibre either from the barks, or even from the raw fibre, generally boiling solutions of alkalis (either carbonate or caustic soda) are used, and the alkaline treatment is followed by one of souring with hydrochloric acid. Others employ bisulphite or sulphurous acid solutions, under pressure. The method which I propose is the following:—The raw fibre, from whichever process, is treated with boiling alkaline solutions (a method employed for the purpose from time immemorial by the Chinese). It is then generally washed, and the material is immersed for a few hours, or even a day or two, in cold weak solutions of bisulphite of soda or lime, or even in sulphurous acid. The fibre is then washed, boiled again with alkalis, and this is repeated with the bisulphite bath if necessary. The bleaching can then be effected by means of solutions of sodium, potassium, or magnesium hypochlorites, but the bleaching powder (chloride of lime) must in all cases be avoided.

In general the bleaching of China grass or rhea fibre is very similar to that of linen, and the same precaution must be taken in the employment of the hypochlorites; but provided that the impurities have

been carefully removed beforehand by the proper scouring process, the bleaching itself does not offer any difficulty whatever, and can even be effected much more readily. The fibre in fact stands, as regards stability, between linen and cotton towards bleaching solutions.

For the scouring either of the raw fibre, or even of the bark of the stems, the usual scouring agents may be employed. Besides carbonate or caustic soda, caustic lime can be very well used for the first boiling. Working in kiers under pressure in the ordinary way will also be found to expedite matters, as might be expected. Rosin soap can also be very effectually used, and so can the mineral acids so largely employed for cotton bleaching.

In dyeing no great difficulty is experienced in the fixation of colouring matters on the fibre. This cannot be so readily dyed as cotton, but in this respect it resembles more closely linen. Turkey reds cannot be very well produced by the new process with oleine, while very good colours are obtainable with the older method of oiling with olive oils. Aniline colours require, as on cotton, mordants for their fixation, and give very good and bright effects; but metallic colours, such as chrome yellow, spoil the look of the fibre by depriving it of lustre. It must also be observed that in dyeing the fibre before spinning the lustre is not lost, whilst this is very often the case if it be dyed in the yarn.

Printing so far has only been tried to a small extent on fabrics produced with this fibre, but I do not apprehend any difficulty in this direction.

Special care will have to be taken in the finishing, especially of heavy goods. It must be remembered that the fibre is not so elastic as cotton, and consequently it must not be exposed to such heavy pressure.

It will be necessary to observe that the dry stems will yield about 10 to 15 per cent. of pure bleached fibre ready for spinning, and it may be asked what is done with the other portion of the stem or the woody part.

So far the wood has not been utilised except as fuel or as manure along with the branches and the leaves of the plant. The leaves have also been used as food for cattle. It had occurred to me that since for every ton of fibre which is produced there are generally four to six tons of wooden sticks, to ascertain if these could be utilised for some industrial purpose. I find that these sticks could be very well employed in paper making, at all events for the manufacture of special kind of wood pulp.

As can be seen from some of the specimens exhibited, a peculiar kind of paper can be obtained which is in some cases very stiff and requires no size in its production. Very likely this is due to the natural gum which is contained in the plant, and which, as well known, imparts to the raw fibre considerable stiffness.

In my experiments on this woody portion, I have been struck by the similarity of the structure of the bark containing the fibre to that of the stick. These constituents behave to chemical reagents alike, excepting that the wood requires a more severe treatment for its disintegration, and especially for its bleaching.

Bearing in mind the possibility of the utilisation of this wood for the manufacture of wood pulp and for other purposes, it will be seen that the methods I proposed for the decortication, or for the separation of the bark, will be found to possess the advantage that

the wood will have already undergone a certain amount of treatment which, by depriving it of some of its soluble constituents, effects a reduction in weight and cheaper transport.

From a commercial point of view, if we have two marketable articles produced, both the fibre and the wood pulp instead of only the fibre, then the question of the cultivation of the plants is raised to a still higher platform of probable financial success.

DISCUSSION.

Mr. THOMSON asked the author why he advocated a preliminary treatment of the fibre with caustic soda, seeing that it must materially increase the expense? If it were true that the fibre in its green state could be easily stripped off the stem, surely that would be the best mode of treatment. Also if the sun were not sufficient to thoroughly dry the bark, might it not be dried in an oven, for heating which the refuse pith or decorticated stem would serve as fuel? It would bear transit without fear of fermentation. After many experiments he had come to the conclusion that bisulphite of lime was a much better antiseptic than bisulphite of soda. As regarded the percentage of fibre in the green stem as given by the author, he thought it high, his impression being that it was about 3 per cent. or one ton of fibre for every 33 tons of green stems.

Mr. SANSONE, in reply to Mr. Thomson, said that when the bark of the stem is peeled off by hand, and dried, on long sea voyages, when exposed to moisture, it readily begins to ferment. Thus sometimes fibre is spoiled. For this reason it has been suggested that the stems should be boiled in carbonate of soda. If treated in this manner they might just as well boil the stems, the wood portion of which possibly could be used for paper making, and in this case there would be something gained. I do not apprehend any difficulty with regard to the application of bisulphite of lime on the spot, as the process is not so complicated, but such as the natives of India would be able to use. Again, it might be carried out under the superintendence of competent men sent out for the purpose. There is another point which deserves attention at the hands of the chemist, and that is in reference to a kind of coagulation which takes place in the stem on steaming or boiling. What the product is which is coagulated, I am not able to say, but it forms a problem well worthy of solution. Dr. Forbes Watson mentions, in a report, on Rhea published some years ago, that in some experiments made in India on the green stems with the Greig machine, the cylinders were coated with a kind of gum so hard that it had to be broken off with a chisel. The industry was introduced into England about 1840, and this material has been worked for years in Bradford and Manchester, and is being used pretty extensively at the present time. One reason why it has not been extended more is owing to the irregularity of supply from China, where the process of scraping the bark from the stem with a knife is a very slow method, and up to within a few months ago it was not possible to treat the fibre on a commercial scale. Recently, however, the raw material has been produced on a larger scale, and proper methods are in vogue for working it. Again, we must not confuse China grass with Rhea fibre. Rhea grass is what they are trying to cultivate on a large scale in India and other countries where the soil is more suitable, and I should not be surprised to see shortly sufficient quantities coming into our markets, to make it worth the while of anyone to work up.

RECENT CONTRIBUTIONS TO THE ESTIMATION OF TANNINS.

BY H. R. PROCTOR, F.C.S.

IN more than one paper read before this Society or its predecessor, the Newcastle Chemical Society, I have expressed the opinion that Löwenthal's process for the estimation of tannin based upon its oxidation with permanganate in presence of indigo, was to be preferred for general use to any other yet proposed. This is probably still the case, but longer experience has demonstrated that there are certain inherent defects in the method, which preclude its ever being of the highest scientific accuracy, and which require strict attention to ensure even the degree of exactness which is needed for technical purposes.

The first of these points is that the quantity of permanganate consumed is largely dependent on the rate at which it is added. To account for this, it does not seem necessary to adopt any complicated hypothesis as to the "speed of chemical action." The simple fact is, that the oxidation is not a complete one, like that of oxalic acid, in which the end-products are simply carbonic acid and water. When the whole of the indigo is decolourised, it may be taken for granted, under the conditions of the process, that all the astringent and other matters more readily oxidisable than indigo are also destroyed, but there remain in the solution products of this decomposition which, though less easily oxidised, will still readily reduce permanganate when indigo is absent. If, therefore, in the course of the titration, permanganate be rapidly added, it will destroy the indigo with which it comes in contact, and then proceed to further oxidise these products of decomposition, thus leading to too high a result. It is also obvious, that even in the most carefully conducted titration, more or less of this action will take place, and in extreme cases the variation so introduced may amount to more than 30 per cent. of the total.

To investigate this and other causes of discrepancy, and, if possible, to agree on some standard method by which they should be excluded, in 1883 the Association of German Tanners invited the principal German experts to hold a conference on the subject in Berlin. The result of their deliberations has appeared in the past year in the form of a report,* consisting mainly of a valuable study of the process, by Prof. Von Schroeder, and a description of his modifications, which the Commission recommend for general adoption.

The most important part of the report is that dealing with the error of which I have already spoken.

* Bericht über die Verhandlung der Commission zur Feststellung einer einheitlichen Methode der Gerbstoffbestimmung, Cassel, 1885.

While it is evident that it is impossible to establish a definite value for tannin, as compared to oxalic acid, it is obvious that if the permanganate be standardised against a solution of pure tannin, under rigidly the same conditions as those of the actual analysis, the error introduced will be the same in both cases, and will consequently be cancelled. The practical difficulty in this is that absolutely pure tannin is unattainable, the purest article to be met with in commerce being largely contaminated with gallic acid and other impurities. Prof. Von Schroeder has met this difficulty in a most ingenious way. As gallic acid consumes slightly more permanganate than an equal weight of tannin, such an impure tannin gives a result differing but little from that of a pure sample, but reduces slightly more permanganate; so that, taking the average of six of the purest German sorts, 1000 of dry commercial tannin reduced the same quantity of permanganate as 1048 of the tannin precipitated by hide, as determined by careful analysis by Hammer's method. Prof. Von Schroeder, therefore, determines simply the permanganate consumed by 10cc. of a solution containing 2grms. per litre of air-dry commercial "pure" tannin, calculates the dry matter, and multiplies it by the round number 1.05 to obtain the value in actual tannin precipitable by hide. It is not found necessary to determine the moisture in the tannin used for each analysis, as air-dried tannin in a well-corked bottle remains long unaltered. To determine whether a given tannin is pure enough to be used in this way, 2grms. of the air-dried tannin is dissolved in a litre of water, 10cc. of the solution are titrated, and 50cc. are digested 18—20 hours with 3grms. of moistened hide powder, with frequent shaking; 10cc. of the filtrate is then titrated, and if the permanganate it consumes amounts to less than 10 per cent. of the total consumed by the tannin, it may be taken as being one of the best of commercial preparations, and suitable for the purpose in view.

Ingenious and practically accurate as this method undoubtedly is, there is something scarcely satisfactory in using an impure substance to standardise with; and as gallotannic acid is, after all, not identical with most of the tannins we have to determine, there seems no special necessity for its use, if a body of more definite composition can be found which is similarly oxidised in presence of indigo. Such a body, I think, we have in gallic acid, which, from its ready solubility in boiling water, is easily purified by crystallisation. It gives a very sharp end-reaction in presence of indigo, and is quite as closely allied to many of the natural tannins as gallotannic acid itself. More experiments are needed to determine whether the relative values of tannin to gallic acid and permanganate are constant ones under all conditions, but the mean of a considerable number of titrations give 1.35grm. of pure tannin (as calculated by Prof. Von Schroeder's method) as equal in reducing power to 1.00grm. of ordinary crystallised gallic acid.

The tannin used was Schering's Ph. Ger., which was found by Prof. Von. Schroeder the best of all he examined; but my sample, obtained through Dr. Roth, of Berlin, does not seem so pure as his, leaving after prolonged treatment with hide-powder a residue unabsorbed equal to 11.1 per cent. of the total permanganate used.

As an additional safeguard, besides standardisation with tannin, Prof. Von Schroeder proposes the general adoption of a mode of titration which he calls the "one cubic centimeter method," and which consists in the addition of the permanganate solution, 1cc. at a time, with vigorous stirring after each addition, till the colour of the liquid indicates that a few drops only are required to end the titration, when it is added drop by drop till the reaction is complete.

Though this method, when uniformly carried out, gives constant results, and will, therefore, like any other fulfilling this condition, give accurate values when employed both for standardising and analysis, it seems to me, even as compared with the usual drop method, to be a step in the wrong direction both theoretically and practically. Instead of endeavouring as far as possible to prevent the secondary oxidation, it attempts to fix it at a definite but rather considerable amount. Taking Prof. Von Schroeder's own numbers, the increased secondary action, as compared with the drop method, amounts to 18 per cent. of the total permanganate, and, according to all scientific analogy, this considerable quantity must be subject to far larger fluctuations from accidental circumstances than one tending very closely to an irreducible minimum.

Further, if we accept the explanation which I have offered of the causes of this secondary action, it will be obvious that it is not dependent directly on the mere time of titration, but rather on the rapidity of mixture; and that hence the 1cc. method would be influenced far more than the drop method by the vigour of the stirring. This proved to be the case. In order to test it, I constructed a special stirrer, consisting of a perforated earthenware disc, approximately fitting the beaker, and worked up and down in it like a piston by a glass rod. To avoid repetition, I give the results of one series only of titrations, which were performed alternately with the disc stirrer and an ordinary glass rod.

20cc. Indigo alone—

	Drop Method.	1cc. Method.
With disc stirrer	{ 5.6 5.7 5.6 5.6	(disc worked continuously)
With glass rod in beaker.....	{ 5.65 5.75 5.6 5.75	(stirrer at rest while actually adding permanganate.)

20cc. Indigo 5cc. Infusion—

With disc stirrer	{ 14.3 14.3 14.4 14.5	(as before).
With glass rod in beaker	{ 14.6 15.5 11.7 15.7	(as before).

For comparison, I also give the result obtained by drop method, in basin with rod—viz., 14.8, 14.7, from which it appears that mixture in a basin is slower than in a beaker with a rod stirrer.

From these numbers it will be seen that both indigo alone, and more especially mixtures of indigo and tannin, give very different results according to the vigour of the stirring, and that these variations are, as might be expected, much greater with the "1cc." than with the "drop" method, and also with the simple rod than with the much more efficient disc stirrer. As such irregularities of stirring are more or less unavoidable in all titrations, there seems strong reason for preferring the "drop" to the "1cc." method; but whichever be adopted as a standard, it is imperative that the method of stirring be strictly defined.

Although I adopted the disc stirrer at first as an experiment, I have found it answer its purpose so effectually that I now employ it in all my analyses, and find it greatly conduces to constancy of result, and the white earthenware disc makes the change of colour of the liquid very visible.

I have found, however, that even with the disc stirrer it is possible, by varying the rate of addition of permanganate, to materially alter the results; and I have adopted a plan which seems to overcome this difficulty very satisfactorily for practical purposes. Instead of attempting to regulate the speed of flow by the tap of the burette, I draw out a small piece of quill tubing to a capillary point, and attach it to the bottom of the burette with indiarubber tube. If

the small tube fits like a cap on that of the burette, it comes very little in contact with the permanganate, and is very slowly affected by the weak solution (1grm. per litre) which I employ. When I have finished an analysis I always remove it, and place it in a little of the dilute acid solution of a finished titration, not only to save the rubber, but to dissolve any oxide of manganese which might be deposited in the point, and so affect its flow. The solution in use flows at first in a capillary stream, and as the pressure is reduced it begins to drop; but if approximately the same quantity is used, and the burette is fresh filled for each test, the rate of delivery is very uniform, and it seems not to affect results even if it be so slowed as to drop throughout the titration. My tube delivers the first 10cc. in about 100sec. Of course, it is necessary to employ a perfectly clear solution of permanganate, and it is desirable so to arrange the strengths or quantities of tannin infusion that about the same proportion of permanganate may be used in the actual analysis as in the standardising.

As it is possible, using a 25cc. burette, to read to $\frac{1}{20}$ th cc., which is a decidedly smaller quantity than the unavoidable errors from uncertainty of end-reaction and other causes, there seems no use in employing so large a quantity as 20cc. indigo solution in $\frac{1}{2}$ litre water, and a considerable saving of time is effected by halving the quantities without, I think, any less exactness. I find, also, that I can obtain greater accuracy by titrating to a primrose yellow than by going further, as in the first case an additional drop makes a distinct difference, while when the indigo is all destroyed additional permanganate makes no permanent change. As it is not possible to retain a definite tint clearly in the memory, I take a beaker full of the yellow liquid of a complete titration, to which slight excess of permanganate has been added, and, after allowing it to stand a little, I add one drop of indigo, and place it beside the beaker in use for comparison.

The second point of difficulty to which I alluded at the beginning of my paper, is the removal of the tannin. It will be remembered that permanganate oxidises all astringents and many other bodies in presence of indigo, and that it is therefore necessary to remove the tannin from a portion of the liquid and make a second titration, so as to obtain the tannin by difference. One of the earliest, and possibly one of the best, ways of doing this—though, as I shall show, it has one very serious defect—is by the use of finely-powdered hide. This method has been very carefully studied by Prof. Von Schroeder, and the Commission seem to have determined, almost without discussion, that it was to be employed in preference to gelatin or any other solution to effect the separation. Von Schroeder directs that 3grms. of hide powder should be softened for about 20 hours in distilled water, collected on a washed linen filter, washed repeatedly with distilled water, and squeezed in the linen first with the fingers and then in a clean pocket-handkerchief. The moist hide is now easily made into a ball with the fingers, and introduced into a flask of about 150cc. capacity; 50cc. of extract, which must not contain more than 0.1grm. of tannin, is added, the flask well corked, and the whole allowed to digest, with frequent shaking, for 18 or 20 hours. The liquid is then filtered, and 10cc. titrated like the original extract, when the loss gives the permanganate equivalent of the tannin absorbed. Von Schroeder shows by experiment and calculation that the water introduced with the hide may be disregarded without introducing sensible error.

If hide powder is to be used, it is of the utmost importance that it should be properly prepared and purified. Detailed directions for this are given in

the report, but as the process is somewhat troublesome, especially for small quantities, most chemists will be glad to learn that it may be obtained, of excellent quality, both of Dr. Roth, of Berlin, who has undertaken to prepare it according to Prof. Von Schroeder's directions, and from the *Versuchstation für Lederindustrie* in Vienna, and Messrs. Mawson & Swan of Newcastle, have kindly undertaken to keep it in stock, together with the other articles required in tannin analysis. This hide powder is very white and light, and gives up nothing to water capable of affecting permanganate in the Löwenthal test, and, indeed, so little matter of any sort, that the Vienna *Versuchstation* is now employing a method of analysis dependent on evaporating of a given quantity of the infusion before and after absorption, and weighing the residues of absorption.

It is a distinct disadvantage of this method for technical purposes, that so much time is required for its execution as often to make its use impracticable in the limited time allowed for decision on the relative merits of different samples. A more serious defect, however, is that hide powder absorbs gallic acid freely. I showed, in a paper on "Müntz and Ramsbacher's Apparatus for the Estimation of Tannin," read before the Newcastle Chemical Society in March, 1876, that raw hide is capable of withdrawing most acids from their solutions, to form the sort of molecular combination which leads to the swelling of the hide. In an experiment there quoted, as much as 41 per cent. of gallic acid was removed from a dilute solution. It was therefore a matter of no great surprise to me that a solution of gallic acid containing 2grms. per litre, when treated with hide powder, as directed by Von Schroeder, lost 55 per cent. of the total gallic acid it contained. This fact seems to put hide powder completely out of court in estimating tannin materials containing gallic acid.

Mr. Bertram Hunt, in a valuable paper, vol. iv. p. 263 of the Journal of this Society, points out that gelatin solution, followed by saturation with salt and addition of acid, as proposed by me, also precipitates a portion of gallic acid amounting to about 17 per cent. I can quite confirm this result, and the error, though less than that caused by hide powder, is a sufficiently serious one. Mr. Hunt proposes to remedy it by using only 25 per cent. of a saturated solution of salt, instead of saturating the whole mixture, and he shows that by this means the precipitation of gallic acid is almost *nil*. This method is very similar to Löwenthal's original one, and identical with my earlier practice. I only adopted the saturation method after it had been proved by Simand* that gelatin tannates were soluble to a small extent, varying with the nature of the tannin, in this unsaturated salt solution, and that consequently larger or smaller results were obtained according to the concentration of the tannin infusion employed. It was to obviate this, and not for the sake of getting a clear filtrate—which, in fact, is more easily obtained without saturation—that I adopted the saturating plan, and it was its adoption which rendered the use of kaolin a necessity. If, therefore, we return to the use of unsaturated solutions, we have to face imperfect precipitation of the tannin, while if we saturate we precipitate a portion of the gallic acid, if any be present; and, of course, by choosing a proper concentration in any given case the two errors will compensate each other, and yield an apparently accurate result. This is a very unfortunate state of affairs, and a more satisfactory mode of separating tannin is a great *desideratum*. The error is not, however, of so great practical importance as it looks,

* Dingl. Polyt. Journal, Bd. 224, S. 400.

since the total of gallic acid is in most tanning materials only a small one.

In the discussion which followed Mr. Hunt's paper, it was pointed out by several chemists that the gelatin method did not give satisfactory results as to the value of tannins for dyeing purposes. This is only to be expected. There is a great variety of tannins and "tannin colouring matters," all of which are taken up by hide and precipitated by salted gelatin, but by no means all give good blacks with iron, or will precipitate tartar emetic. With such varied and little understood bodies as the tannins, the mode of analysis must be chosen in relation to the use to which the materials are to be put. If the object is to precipitate antimony, naturally Gerland's tartar emetic method is more likely to give good results than a gelatin process. If ink-making or dyeing black is the requirement, Handke's process with ferric acetate, or a colorimetric method, would suggest itself. If fixing aniline colours is required, an aniline colour, such as methyl-green, may be used as a precipitant. In all these methods we are not really determining the quantity of a given ingredient present, but the activity in a special direction of a mixture of various compounds. It is therefore most essential that the chemist should specify not only his results, but also how his results are obtained.

In the case of most tannin materials the sampling, grinding, and extraction are as important, and as likely, if unsystematically carried out, to lead to discrepancies, as any other part of the process. As the German Commission make no fresh suggestion on the two former points, and I have already discussed it pretty thoroughly in my recent book on tanning,* I need not here enter further into the matter. For extraction, Von Schroeder has invented a very neat little apparatus, which has been adopted by the Commission, and of which I have an example on the table. It consists of a perfectly cylindrical vessel of cast tin, about 12.5cm. high and 7cm. in diameter, and furnished with a spout. Into this fits a perforated strainer or piston, which in use is covered with muslin, and which must move freely up and down, but fit sufficiently closely to compel all the liquid on depressing the piston to flow through the strainer. 5, 10, or 20grms. of the material, according to its strength, is weighed into the extractor, covered with 200cc. of distilled water, and allowed to remain, with occasional stirring, for 12 hours. The piston is then pressed in, and the clear extract poured into a little flask, and replaced by 200cc. of boiling water. On drawing up the piston the water passes through and rinses it, and it may then be laid on a plate, or set slanting in the mouth of the extractor till again required. The extractor is then heated in the water-bath for half an hour, with occasional stirring; the liquor is pressed out and poured into the litre flask, and the process repeated five times in all. Evaporation will still allow of the extractor being rinsed out with small portions of water, and, after cooling, the flask is filled up to the mark, and if necessary filtered. Where liquids are obstinately turbid, the addition of a little kaolin, as suggested by the writer, and approved of by Von Schroeder, will enable a clear filtrate to be obtained.

Directions for the separation of "easily" and "difficultly soluble" tannins by cold extraction with the Real's press or percolator are given, but as no attention to this point has been paid in England, and it seems one of very doubtful importance, the reader is referred to the original paper for details.

In my own work it is frequently essential that results should be known within 24 hours of the time of

receiving the sample, and I am, therefore, unable to adopt Professor Von Schroeder's method of extraction. I find, however, that brisk boiling for half an hour in a large flask with a litre of water, cooling, rinsing into a litre flask and making up to the mark, as described by me in a previous paper, is not only a very rapid but a very thorough and uniform mode of extraction. I hope when time permits to make a careful comparison of the two methods, but in the few experiments I have yet made, simple boiling has given fully as complete an extraction as the Von Schroeder extractor. I may remark that it is quite unnecessary to filter the liquid before making up to volume, as the bulk of the material employed introduces no sensible error, while filtration and washing consume a great deal of time. Of course, after making up to bulk and thoroughly shaking, the quantity required for actual use must be passed through paper.

ON AN ALLEGED ERROR IN USING THE NITROMETER.

BY G. LUNGE.

IN No. 1362 of the *Chemical News* (vol. 53, p. 6), Mr. Thomas Bayley again asserts that erroneous results are obtained in using the nitrometer, owing to the solubility of nitric oxide in the acid liquid, unless the liquid contained in the apparatus at the end of the operation is diluted with water. My experiments, intended to prove the contrary—viz., that no such dilution is required in order to obtain accurate results—are represented as being beside the mark, since I had "overlooked the all-important fact that the liquid floating upon the mercury contained in a nitrometer is not pure sulphuric acid, but a solution of mercurous nitrate in sulphuric acid." "Now the ordinary text-books and works of reference (*e.g.*, 'Watts' Dictionary,' 'Gmelin's Handbook,' etc.) credit the subsalts of mercury and other metals with the power of dissolving nitric oxide gas." Over and above these remarks, Mr. Bayley quotes the results of experiments made by a gentleman whose name is not mentioned (and whose authority, therefore, must be held in abeyance), and some of his own. In the latter he obtained an additional 0.5 or 0.45cc. of NO by diluting the liquid at the end of the experiment; in the second set of experiments he allowed the gas to escape, so that only liquid remained in the tube, and on adding water to the liquid he invariably obtained a further liberation of NO. Lastly, he made the experiment of passing dried NO through a solution of mercurous sulphate in strong sulphuric acid, when 14.678grms. of acid gained 0.0098grms. of NO (?).

I am sorry I must still disagree from Mr. Bayley; I must re-assert that no such error exists as is maintained by him, and that his own results cannot be accounted for otherwise than by experimental errors, such as I have seen to occur times out of number to my students before they had thoroughly mastered the handling of the nitrometer, and as have sometimes occurred to myself, although I could not possibly overlook them, and hence always condemned such tests as useless.

Let us see what evidence Mr. Bayley adduces in his favour. First of all come "the ordinary text-books and works of reference," which are said to mention the solubility of NO in the subsalts of mercury and other metals. Now even if they did, that would not be decisive, for it is quite clear that an aqueous solution of such subsalts (and another would not be meant) might and probably would behave

* "A Text book of Tanning," by H. R. Procter. Spon, 1885.

quite differently from strong sulphuric acid containing a little mercurous sulphate in solution. But do "the ordinary text-books and works of reference" state what Mr. Bayley asserts? I have looked through all the very numerous text-books and works of reference in my library, English, French, and German, but not in *one* case have I found a word about mercurous salts being solvents for NO. It is true "Watts' Dictionary" and the English edition of Gmelin are not in my possession, nor could they be obtained here. I have therefore drawn upon the kindness of my friend Mr. John Pattinson, who has found the places in Watts and Gmelin mentioned by Mr. Bayley, but who has equally found no further mention of the alleged fact in any other of the handbooks consulted by him. He has sent me a verbatim copy of the quotations in question, from which it appears that they are not very convincing. In "Watts' Dictionary" it is said: "Nitric oxide is likewise absorbed by stannous and mercurous salts, and forms crystalline compounds with stannic chloride and with sulphuric acid or anhydride." The last half of the sentence seems to show that it does not refer to the solubility of NO in aqueous or other solutions of salts, but to its combination with certain bodies, in which distinct compounds are formed, not by simple addition, but connected with chemical changes (as when NO combines with SO_2 , when SO_2 is given off).

In "Gmelin's Handbook" the solubility of NO in mercurial salts is only mentioned when describing the preparation of NO in the *liquid* form, under a pressure of from 20 to 50 atmospheres, by means of copper and nitric acid within a sealed bent tube: "Mercury cannot be used instead of copper in this case, because the mercurial solution absorbs the nitric oxide gas, so that the pressure never rises above two atmospheres." That this observation (which is not mentioned in the latest German edition of Gmelin, by Kraut) has very little to do with the reactions in the nitrometer is quite evident.

Since these quotations certainly do not decide the question at issue, we shall have to have recourse to the ultimate and assuredly the only criterion—that is, the experiment, all the more as it is a very different thing whether NO is soluble in a liquid, and whether it is driven out by dilution with water. Mr. Bayley thinks that the heat generated in that case would drive out the nitric oxide; but then it would be absorbed again during the cooling down of the apparatus. In any case we need not trouble ourselves on that head, if we can prove that *no gas is given off at all by diluting the liquid*, and this is most certainly the case *when the operation in the nitrometer has been properly conducted*.

I have made quite a number of experiments by treating ordinary nitrous vitriol in the nitrometer, at the end of which, after proper cooling and levelling and reading off, I added water amounting to from half to the whole of the bulk of the acid liquid; after shaking, cooling, and properly levelling again (as tested by the immovability of a column of water in the narrow part above the tap, when very cautiously opening the latter), *the volume of gas was always found absolutely the same as before*. In point of fact no bubbles of gas were given off when the water and acid got mixed.

I have also repeatedly tried the second kind of experiment made by Mr. Bayley—viz., shaking nitrous vitriol in the nitrometer till the reaction was complete, allowing the gas to escape, so that only the acid liquid remained above the mercury, and adding water equal in volume to the acid liquid. But apart from the first case, which instantly opened my eyes to the possible source of error, *I never obtained any liberation of gas whatever by this method*.

Lest my results should appear biased by my previous utterances in this matter, I requested my friend, Professor Treadwell, of the Analytical Laboratory of the Polytechnicum, to repeat my experiments, and he empowers me to state that he also found no evolution of gas on diluting the acid liquid with water. Lastly, in order to convince myself whether any special manipulative skill, such as a professor may be credited with, was required to avoid the error into which Mr. Bayley and his anonymous friend have fallen, I had the experiments repeated by one of my students, Mr. Karl Schniter, who had never had a nitrometer in his hands until the day before. Of course I explained to him how to avoid mistakes, and he also confirmed our previous results in every way. After this I did not think it worth while repeating Mr. Bayley's experiments in which he found that 14.678 grms. of sulphuric acid, holding some mercurous sulphate in solution, and being contained in a Geissler bulb-apparatus, gained 0.0098 grm. in weight when dry (?) NO was passed through it from time to time. That slight increase in weight of a glass apparatus filled with strong sulphuric acid does not seem to carry much conviction.

I shall not venture to hazard a guess by what fault of manipulation the erroneous results obtained by Mr. Bayley and his friend may have been caused, but I think it only right to point out to the very numerous class of chemists who employ the nitrometer, and more especially to the less experienced among them, what is the most probable source of error with that apparatus. Leaving out of consideration such things as insufficient cooling, wrong levelling, leaky taps, and the like, I would draw special attention to one point which has caused me to reject very many of my own tests, and which I have often found to be insufficiently appreciated by my students. When shaking the acid and mercury, it generally occurs that a drop of acid pertinaciously clings to the narrow part of the tube immediately below the tap. Unless this drop of acid is caused to flow down by jerking, shaking up, and several times repeating this operation, so that the mercurial froth gets quite up to the tap, a portion of the nitrous acid will escape decomposition. This is easily noticed when successively forcing out the gas, the acid liquid, and at last a little mercury through the tap. As soon as the mercury reaches that narrow part, where an undecomposed drop or film of acid had lodged, there will be a slight effervescence, and this furnishes proof that the test has been low. If, however, after the ordinary shaking, settling, and reading off, some water were run into the tube, it would wash down that undecomposed acid and, on shaking with mercury, some more nitric oxide would be given off. That may be 0.5, as Mr. Bayley has frequently found, or more or less, according to the original fault in manipulation.

Again, when allowing the gas to escape and then adding water to the acid, you may easily obtain an additional 0.5 of gas, or even far more than that, by either of the following mistakes. If, on letting out the gas, the pressure for a moment became too low (as happens very easily), some air would enter into the tube and get mixed with the nitric oxide; this would instantly form higher oxides of nitrogen, which would be just as instantly absorbed by the acid within the tube, and, of course, give off more NO after diluting and shaking up with mercury. But even if this had been avoided, the nitric oxide would unite with oxygen in the cup surmounting the tap, and the products would be partially retained by the acid film covering the inside of the cup. If it was neglected to rinse the cup *most thoroughly* before adding the water in Mr. Bayley's second experiment, the water would be charged with a little nitrous acid, and would, of

course, give off nitric acid within the nitrometer. When the precautions just mentioned are thoroughly observed, and, of course, the apparatus is otherwise properly manipulated, there is no sensible quantity of NO either retained in the acid at first (as proved by hundreds of tests with pure materials) or liberated by a subsequent addition of water.

As I do not wish to protract this controversy any longer, I expressly declare that I neither affirm nor deny the fact that the nitrometer acid may keep minute quantities of nitric oxide in solution; but I affirm that these quantities must be, in any case, so minute as to be inappreciable in practical work, and I deny that the addition of water causes the operation to be more correct by the liberation of a sensible quantity of nitric oxide, previously dissolved in the acid liquid.

DISCUSSION.

MR. JOHN PATTINSON: My assistant, Mr. Laidler, and I have very carefully repeated Mr. Bayley's experiments as described by him in the *Chemical News* of January 1, 1886, and the results we obtained confirm the accuracy of those obtained by Dr. Lunge and Dr. Treadwell. 3.564grms. of nitrate of potash (equal to 3grms. of nitrate of soda) were dissolved in 5½cc. of water, and the solution was made up to 100cc. by the addition of pure oil of vitriol. 3cc. of this were placed in the nitrometer, and 3cc. of pure oil of vitriol were afterwards added to rinse out the cup of the nitrometer. This liquid on being shaken up with the mercury yielded 24cc. of nitric oxide gas, which is just about the proper amount that should be obtained. (I notice Mr. Bayley says that from 3cc. of his solution of nitrate of soda only 7.8cc. of NO gas was obtained. There is some error here. Probably only 1cc. of the nitrate solution was taken instead of 3 as stated.) After expelling the 24cc. of NO from the nitrometer, the cup was rinsed out with water and afterwards dried with blotting paper, and every precaution taken to avoid the possible errors pointed out by Dr. Lunge in his paper. The acid and mercurous salt were now diluted with an equal bulk of water and shaken. At first no additional gas was liberated, but after standing some time an occasional extremely minute bubble of

would be of about sp. gr. 1.620. This yielded 10.70cc. of NO in the nitrometer. On removing this gas and diluting the remaining solution with an equal bulk of water in the nitrometer and agitating, no further gas whatever was obtained. I am quite satisfied that the results obtained by Mr. Bayley and his friend have been owing in some way to imperfect manipulation.

Notices of papers and communications for the meetings to be sent to the Local Secretary.

Meeting held January 27, 1886, in the Mason College.

MR. CHARLES HUNT (TREASURER) IN THE CHAIR.

NOTE ON THE DETECTION OF METALS IN DRINKING WATER.

BY A. J. COOPER.

(Abstract.)

THE tests described in the following paper have long been used as means of qualitatively detecting the metals to which they respectively refer. The object of the experiments undertaken by the author was to ascertain the comparative delicacy of these tests, with a view to their application quantitatively.

The following table sets forth the results obtained:—

METAL.	REAGENT.	Depth of Liquid 3½ inches.	Depth of Liquid 14½ inches. Cylinder enclosed in opaque tube.
		1 part of metal detected in	1 part of metal detected in
Copper	K ₄ FeCy ₆	4,000,000 of water	11,750,000 of water
"	NH ₄ HO	1,000,000	1,950,000
"	H ₂ S	4,150,000	15,660,000
Zinc	NH ₄ HS	2,500,000	—
Arsenic	SH ₂	3,600,000	7,520,000
Lead	K ₂ CrO ₄	4,000,000	5,875,000
"	SnH ₂	100,000,000	196,000,000

gas could be seen by the aid of a magnifying glass ascending up through the liquid. The whole amount of such gas, after shaking the nitrometer and allowing it to stand 15 hours, was unmeasurable, and formed a minute bubble in the narrowest part of the tube, immediately below the tap. There certainly could not be more than what would probably measure 0.01cc. So that practically there was no further evolution of gas from the liquid after dilution. Another experiment was made, in which 2.5cc. of a solution containing 0.045grms. of nitrate of potash were added to one-and-a-half times its bulk of oil of vitriol (or 3.75cc.), thus making a solution which

ON THE CORROSION AND PITTING OF COPPER AND BRASS BY SALINE WATERS.

BY WILLIAM A. TILDEN, D.SC., F.R.S.,

Professor of Chemistry in the Mason College, Birmingham.

In the Philosophical Transactions for 1824 there is a paper by Sir Humphry Davy, under the following title:—"On the Corrosion of Copper Sheathing by Sea-water, and on Methods of Preventing this Effect; and on their Application to Ships of War and other Ships."

This paper contains an account of an experimental enquiry undertaken at the instance of the Commissioners of the Navy Board, and in co-operation with a committee of the Royal Society; and so far as I can ascertain, it represents the first attempt systematically to investigate the causes of the corrosion, and to find a remedy for the destructive action of sea-water. The results of this investigation are matters of history. Davy was led to apply the theory of electro-chemistry, and knowing that "chemical attractions may be exalted, modified, or destroyed by changes in the electrical state of bodies," he considered that copper, which is "only weakly positive in the electro-chemical scale, if it could be rendered slightly negative, the corroding action of sea-water upon it would be null." Davy's plan of protection consisted in attaching small pieces of zinc or iron to the copper surface; and there is no reason to doubt that so far as the protection of the copper from the attack of the sea-water was concerned, the plan was entirely successful. It failed in practice from the circumstance that the sheathing thus protected was found to become quickly loaded with an earthy deposit, upon which sea-weeds and barnacles gathered more abundantly than under ordinary circumstances when protectors were not employed.

Before Davy's time it had been "generally supposed that sea-water had little or no action on pure copper, and that the rapid decay of the copper on certain ships was owing to its impurity" (Davy, *loc. cit.*); but this opinion could not have been universally held, inasmuch as patents were taken out by Keir in 1779*, and by William Collins in 1807, for alloys of copper with zinc adapted to the manufacture of ship sheathing. In "Aikin's Dictionary of Chemistry" (dated 1807), under the articles *Brass* and *Copper*, the following passages occur:—

Brass is said "to be less subject to rust, and to be acted upon by the vast variety of substances which corrode copper with so much ease; and again "the principal objects of alloying copper appear to be to render it less liable to tarnish, and especially to be acted upon by common animal or vegetable substances, etc.; and Davy himself states that in some comparative experiments of his, he found that the copper containing alloy was attacked by sea-water less than pure copper.

In 1823—that is before the publication of Davy's experiments—a patent was taken out by Robert Mushet, for the manufacturer of a metal suitable for sheathing, by alloying copper with very small quantities (2oz. to 100 pounds) of zinc or tin.

The well-known patent for yellow metal, specially applicable for ship sheathing, was taken out in 1832, by Mr. George Frederick Muntz; but it does not appear to have been maintained that this copper zinc alloy would resist the action of sea-water better than copper. Superiority was claimed for it on the ground that it was cheaper, that it would roll at a red heat, and that ships sheathed with it would be kept cleaner, "because the zinc in the alloy corrodes entirely over the surface, and prevents barnacles, etc., attaching themselves to the bottom of the ship." ("Ure's Dict." vol. i. and Supplement, also Abstracts of Patent Specifications.)

Several other patents have been taken out for copper alloys suitable for ship sheathing. For example, one by John Revere in 1830 (No. 5892), for a mixture of 95 zinc to 5 copper. Another by Matthew Uzielli in 1830 (No. 5952), for an alloy of 100 copper with 5 to 7 parts of tin. And again in 1830, by Geo. Gwinnett Bompas. According to this inventor,

"copper and other metals and their alloys are preserved from oxidation, and rendered suitable for sheathing ships, by using such combinations of metals as will, in sea or saline water, just neutralise the corrosive action of the sea-water, by causing slight galvanic action." From 90 to 200 parts of zinc, alloyed with 100 copper, were recommended for sheathing.

It appears, therefore, to have been believed by many persons that pure copper was not the best material for resisting the action of sea-water, and even at the present time there can be no doubt that considerable difference of opinion exists upon this subject.

My attention was drawn to the matter about three years ago, and finding that the greater part of any knowledge that might exist upon the subject was in the possession solely of Admiralty officials and others, and had not been published, I thought it might be interesting, in a town where so much copper and brass are manufactured, to make known the results of my own observations and experiments. The only observations of any importance that I can find recorded are contained in the first volume of "Percy's Metallurgy", published in 1861, and this has long been out of print. In pages 506 to 517, it contains extracts from official documents relating to the loss per sheet per annum sustained by sheathing, and the results show very fully how variable is the action of sea water upon copper. This variation has generally been attributed to differences in the quality of the copper ("Impurities in Commercial Copper," see Abel and Field, *Journ. Chem. Soc.* 1862, p. 290; and Abel, *Journ. Chem. Soc.* 1864, p. 164), more particularly to the presence of lead, bismuth, and antimony. In these days of iron ships, copper sheathing is a matter of smaller importance than formerly.

One question then relates to a comparison of copper zinc alloys, with commercially-pure copper in their behaviour with sea and other saline waters; but there is another of equal if not greater importance, and that is as to the circumstances under which such unequal corrosion occurs as to lead to the formation of holes in ship sheathing, in the condenser tubes of marine engines, in locomotive boiler tubes, and the like.

For my own information I have made a great variety of experiments on the action of ordinary acids on copper and brass, and have compared the results with those of other experiments which have been published (Calvert and Johnson, *J. Chem. Soc.* 1866, p. 434; Pickering, *J. Chem. Soc.* 1878, p. 112).

It is stated in some books that finely-divided copper will dissolve in hydrochloric acid, with evolution of hydrogen. Not only is this the case, but I find, rather to my surprise, that rolled sheet copper is also slowly dissolved in boiling, strong hydrochloric acid evolving hydrogen gas. With this knowledge it is not difficult to explain the fact, long ago recognised, that brass is capable of being entirely dissolved in hot hydrochloric acid. The zinc is for the most part attached, and the residual spongy copper is then dissolved quite readily.

It was shown by Calvert and Johnson, in 1866 (*J. Chem. Soc.* [2], iv. 412), that an alloy of about equal weights of copper and zinc, immersed in strong hydrochloric acid at common temperatures, gives up in a few days nearly the whole of the zinc, leaving the copper behind in a spongy state. The experiments of these chemists were always conducted with cubes of the cast metals. Mine have all been made upon the sheet, about 1mm. thick; and although my results are not on the whole in conflict with theirs, they do not give in every case the same results. I found that sheet brasses of various composition resist the action of strong hydrochloric acid in the cold better than would appear from the result just mentioned. But a

* Keir, *Jas.*, 1779, 100 copper, 75 zinc, and 10 iron; Collins, *Wm.*, 1817, 100 copper, and 80 zinc. This was cited at the trial of Muntz's Patent.

very curious fact presented itself. I found that if the sheet was bent, a very rapid action set in at the bend, resulting in the disintegration of the metal at that part. After immersion for some weeks, the zinc seemed to have been removed, to a large extent, from the bent part, a brittle spongy mass remaining behind, whilst that portion of the sheet which had not been distorted, remained much less affected; and in the case of a brass containing about 70 per cent. of copper, it was scarcely attacked at all.

Probably all brasses consist of definite alloys, the crystals of which are embedded in an excess of zinc or copper. Bending or distortion of the brass may, therefore, cause the partial separation of the crystals from one another, and the formation of minute invisible cracks, which would admit the acid into contact with the interior of the mass, and so the chemical action would be promoted.

The action of weak hydrochloric acid and of solutions of chloride, is quite different from that of strong hydrochloric acid. The experiments of Calvert and Johnson recorded in the paper just quoted, relate to the action of sulphuric, nitric and hydrochloric acids of various strengths, on copper, zinc and tin, and in several brasses and bronzes. As the metals employed by these chemists were all laboratory specimens, cast and not rolled, and as there are several other points in their paper to which exception might be taken, I felt desirous of further investigating the question for myself, and the following experiments were therefore undertaken.

The metals used were of best selected copper, with commercially pure zinc. They are analysed qualitatively, to see that no unusual ingredient was present, and that the lead and iron which are contained in all brasses, did not exceed the usual minute quantity. Traces of nickel were found in one or two cases. The copper was quantitatively estimated by the electrolytic process, indicating the proportions given in the tables below, which embody some of the results observed.

The metals were polished by rubbing with sand and fine emery. No acid was used to clean them.

It will be noticed that in the three brasses D, E, F, the constituent metals are dissolved away in proportions which are practically the same as those in which they occur in the alloy. In the poorer one C, the zinc is attacked at a much greater rate than the copper; but when the total amount of the attack is considered, it is plain that this mixture is better adapted to withstand the action of weak hydrochloric acid than either of the three which contain more copper.

The action of diluted nitric acid, containing about 6 per cent. of HNO_3 , is shown by the figures in the table below to be different from that of hydrochloric acid, for in this case the attack is greater as the proportion of zinc is greater, and the action of the acid on copper and on the best brass is about the same. The acid employed by Calvert and Johnson was about twice as strong as mine; but their metals were immersed during only fifteen minutes. They point out, however, that the action of the acid is comparatively violent in all the alloys containing an excess of zinc, though much less vigorous in those which contain an excess of copper.

In these results the protective influence of the zinc in the alloy is very manifest. Zinc appears to act in a similar though less effective manner. The conclusions arrived at by Calvert and Johnson as to the action of dilute hydrochloric acid upon brasses, were similar to these, though, inasmuch as their metals were immersed for one hour only, I think their results less satisfactory. My results also agree in the main with observations made by David Mushet about 1822, and afterwards published in the *Philosophical Magazine* for June, 1835, under the title, "On the Immersion of Copper for Bolts and Ship Sheathing in Muriatic Acid as a Test of its Durability."

It occurred to me that when the action of the acid had gone on some time, a portion of the dissolved copper might perhaps be redeposited in exchange for zinc. But from experiments made with the object of testing this point, I came to the conclusion that in nitric acid solutions, so long as there was abundance of free acid present, no appreciable redeposition occurs. When the acid is allowed to become saturated, the surface of the immersed brass becomes coated with a remarkable nearly-black crystalline and highly-lustrous film, which makes its appearance at first near the surface of the liquid, and gradually extends downwards

till the whole plate is covered. It probably consists of oxide.*

I have examined the effect of sulphuric acid upon the same metals, with the following results. No action could be observed below about 150°C . The acid was diluted with water, in accordance with the formula $\text{H}_2\text{SO}_4\cdot 2\text{H}_2\text{O}$.

ACTION OF $\text{H}_2\text{SO}_4\cdot 2\text{H}_2\text{O}$.

The resulting solutions were all black from the formation of sulphide, and on standing, deposited crystals of CuSO_4 . It will be noticed that of the brasses the poor one is the most attacked, and rather singularly the bronze is even more affected.

It is obvious that the extent to which a metal is attacked, depends not only on the composition of the metal itself, but also on the chemical character of the corrosive agent.

Having made these preliminary experiments, I proceeded to inquire into the action of sea-water.

When a piece of copper is immersed in sea-water, the liquid soon exhibits a bluish cloudiness, and after a time, if a portion of the metal is exposed to the air, it becomes covered with a green crust. The composition of this crust was long ago investigated by Sir Humphry Davy (*“Works,”* vol. vi. p. 275), and an explanation given of the process by which it is formed. When the metal is completely immersed in acidulated water, this crust is never formed, the metal dissolving away without deposit. In solutions of chlorides, such as exist in sea-water, the crust is formed to some extent below the surface of the liquid, though in much larger quantity at the surface, and especially upon any part which is liable to be alternately wetted with water and dried in the air.

The action of water and of various saline solutions upon copper has already been to some extent investigated by Dr. Carnelley, and an account of his experiments was read to the Chemical Society of London in 1876 (*Jour. Chem. Soc.* 1876, ii. 1). Dr. Carnelley found that even distilled water, in the presence of air, has a perceptible action upon copper and a minute quantity of the metal is dissolved. He also made a quantitative comparison of the action of solutions of various salts, and showed that the chlorides are amongst the most active. But I could not find that he had given attention to the causes of the inequality of action on the surfaces of metal exposed to the action of salt solutions.

Sea-water is a solution of many salts, together with some dissolved oxygen and carbonic acid. In the first instance I had rather hastily jumped to the conclusion that the ingredient most destructive in its action upon metals must be the chloride of magnesium. I thought it best, however, to test this idea by experiment. Accordingly, chlorides of sodium,

calcium, and magnesium were prepared in a state of chemical purity and free from acid. These salts were dissolved in distilled water, in the proportions in which they occur in sea-water, and strips of the same sample of brass were placed in the solutions, so that a portion of the metal was exposed to the air above the surface of the liquid. The metal in chloride of calcium and in chloride of magnesium remained for many days quite untarnished, whilst that which was immersed in the sodium chloride became very soon encrusted near the surface with green oxichloride, and the liquid grew turbid from the formation of a bluish-green precipitate, becoming at the same time alkaline to test-paper. Obviously the chloride of sodium was by far the most active. I thought this might be due to the much larger quantity of the salt in solution. I therefore made another solution of magnesium chloride of the same strength as the sodium chloride (viz., $26\frac{1}{2}$ grms. to the litre), and placed in it another strip of the same brass. Still there was very little effect. Magnesium chloride is, therefore, evidently not the chief active ingredient of sea-water, and is, in fact, greatly inferior in activity to sodium chloride. This was further confirmed by adding to that solution of magnesium chloride which had been found to be almost inactive a quantity of sodium chloride, when in the course of a few hours the attack commenced.

The action of a chloride upon copper in contact with air appears to depend not solely on the disposition of the copper to combine with chlorine and with oxygen, but is dependent on the affinity of the metal of the chloride for oxygen, and is greater in the case of the alkaline chlorides than in the chlorides of the alkaline earthy metals.† Magnesium chloride probably acts like a very weak hydrochloric acid. As to the influence of the air there can be no doubt. Brass may be boiled with a solution of salt for any length of time without alteration, provided air is entirely excluded. Practical experience in other directions led me to the same conclusion. It has also been long observed that the corrosion of ship sheathing is generally much the worst near the water-line.

The question to which I have especially directed my attention is the remarkable pitting which occurs in brass condenser tubes of marine engines, and in brass and copper tubes generally employed in connection with salt waters. This peculiar pitting, which so frequently leads to perforation of the tube, is a phenomenon unfortunately familiar to manufacturers, but so far as I am aware has not hitherto received adequate explanation.

To account for this pitting a number of hypotheses presented themselves, such as imperfect intermixture of the copper and zinc, the presence of too large a proportion of impurity in the shape of iron or lead, the presence of particles of iron imbedded, during the process of drawing, in the substance of the tube. It was also suggested that vessels lying in dock might take up acid water, which would attack the metal chemically. A long consideration of these and other circumstances led me to the conclusion that even if some of the conditions just mentioned existed commonly enough to account for the frequent occurrence of corrosion, they could not explain the remarkable localisation of the action. The idea occurred to

* Copper is superficially bronzed by formation of oxide when immersed in solution of salt, mixed with potash. Wetzlar.—Schweigger's Journal, 49, 188.

† Davy found that strong salt solutions did not act upon copper, although when diluted they act promptly. I too have noticed that strong solutions of salt act much less vigorously than weaker ones. The only explanation I can give of this fact is that the strong solutions absorb less oxygen than those more dilute. I find from Carnelley's results (*loc. cit.*) that the action of potassium chloride upon copper is somewhat greater than the action of sodium chloride, and this agrees with my hypothesis.

me, as to Davy, Percy,* and others who have reflected upon the subject, that the chemical action of the saline water would be heightened if we imagine the addition of an electrical action, due to the contact of other less positive metals, or other substances in contact with the brass. The difficulty was to account for the existence of such matters in the interior of the condenser tubes.

To test the possibility and the extent of probable voltaic action, as well as the relative powers of different metals to withstand attack of sea-water, the following experiments were made:—Strips (5×2 inches) of the various metals, the composition of which has already been given, were cleaned by rubbing with fine sand-paper. No acid or other liquid was used. They were then placed in beakers, and were about three-fourths covered with sea-water, and, in order to promote the action, kept at a temperature of about 40° C. during seven hours every day (except Sundays). Every few days the loss by evaporation was made up by additions of distilled water. The experiments were started on July 9, 1884, and the metals were removed on June 3, 1885—occupying about eleven months.

It should also be added that the water in the beakers was emptied out several times and replaced by fresh sea-water. To make the results more intelligible to readers of the paper, the metals ought to have been weighed and the loss of weight determined. On removing them for examination, nearly all were covered by a green crust, which was thickest at the top, where the metal had frequently been exposed to the air from evaporation of the solution.

YELLOW METAL D, CONTAINED 61·35% COPPER.

1. *Alone*.—Surface clean and action scarcely perceptible.

2. *Bound with Platinum Wire*.—Very clean. Slight indications of electrolytic action, the course of the wire on one side being marked by small bright patches of deposited copper.

3. *Bound with Copper Wire*.—Slight pitting visible only under a lens. Similar to 1.

4. *Bound with Iron Wire*.—Discoloured with thin films of copper, but otherwise sound. Slightly decayed at bottom edge.

5. *A Spot of Tin attached to Surface*.—Copper deposited all round the tin.

6. *One End Immersed in Black Oxide of Copper*.—The part immersed in the oxide is smooth and polished, as though inequalities had been filled up; but just above the strip is roughened and patches of copper deposited.

A piece of tube treated in the same way was much attacked near the surface of the solution.

7. *One End Covered with Red Lead, Pb₃O₄*.—The part immersed in the oxide looks smooth, but the whole upper part is on one side covered with dots of deposited copper.

BRASS E = 61·98, SAY 62% COPPER.

8. *Alone*.—Clean looking, but under the lens seen to be finely honeycombed: much more attacked than any of the preceding.

BRASS F = 70·22% COPPER.

9. *Alone*.—Finely honeycombed, even worse than 8.

10. *Oxidised Superficially by Heating One End, the other Polished*.—Corroded all over: effect of green incrustation at the top very marked.

COPPER.

11. *Alone*.—Discoloured all over; patches of red oxide, and deeply pitted.

12. *Bound with Platinum Wire*.—Worse than 11; almost entirely covered with crystalline red oxide.

13. *With Brass Wire*.—About the same as 12, the course of the wire being specially marked by red oxide.

14. *With Iron Wire*.—Discoloured, much the same as 12 and 13.

The patches on all these seem to be due chiefly to the action of the green crust.

15. *Spot of Tin near One End*.—Surface pretty clean and not attacked except where incrustation had been allowed to form.

BRONZE (CARRIAGE METAL).

16. *Alone*.—The whole surface finely crystalline (*moirée*); corrosive effect of crust very marked.

17. *With Platinum*.—Much discoloured, black.

18. *With Copper*.—Same as 17.

19. *With Iron*.—Similar to 16.

20. *Sheet of Bronze and Sheet of Yellow Metal D in same liquid in contact with each other*.

Yellow metal not perceptibly attacked, bronze slightly corroded.

The conclusions I draw from the experiments I have described are somewhat as follows:—

1. Copper and brasses containing more than about sixty per cent. of copper are attacked by sea-water and chlorides generally more rapidly than brasses containing about that proportion of copper. I am aware that this conclusion may not be acceptable to everyone, but it is an opinion I have formed after a good deal of consideration, and it appears to have been the opinion of the late Dr. Calvert, to whose paper reference has been made.

2. One cause of unequal corrosion leading to pitting is the voltaic action which is set up in consequence of contact with particles of other less positive metals or metallic oxides. In my experiments, oxide of copper appears to be, in the presence of salt water, one of the most active of these substances.

3. Another, and probably the most destructive agent of all, is the green crust which is produced in the manner I have described, its most abundant formation occurring when the surface is alternately wetted with salt water and dried in the air. The action of this substance may be partly due to its electro-negative character, resembling in this respect oxide of copper; but I incline to the belief that the greater part of its action is a chemical one, aided by its porous texture, in consequence of which it readily absorbs moisture and air. And I believe that the holes in sheathing and in condenser tubes supplied with sea-water are formed most generally in consequence of the formation of patches of this substance. The process is easy to imagine. Suppose the flow of water through the tubes of a condenser to be interrupted for any reason. The tubes lie in a horizontal position and do not drain completely. A small quantity of sea-water is left which speedily dries up in spots, which necessarily lie along one side of the tube in the position in which the holes are most commonly found. Then the moist salt, with the oxygen of the air, acts on the surface of the metal, producing a spot of oxichloride, which remains attached to that part and continues to act electro-chemically when under the surface of the water, chemically by absorption of oxygen when dried up.

It is quite possible, however, that in some cases the process may be started by the presence of other and foreign substances. Suppose a particle of iron to

find its way into one of these tubes. Wetted with water, it at once begins to rust, and will attach itself firmly to the inner surface of the tube. So long as any iron remains unoxidised the effect is to prevent corrosion of the brass, and actually to protect it for some distance all round in accordance with the principle originally established by Davy. But directly the whole of the iron is converted into oxide, the process is reversed. The crust of oxide formed upon the brass and closely adherent to it causes the action of the salt water to be greatly intensified, and the formation of green oxichloride proceeds rapidly. It may also be remembered that when cast-iron is attacked by salt water it leaves behind it a skeleton of carbonaceous matter which probably contributes to the effect. Several other metals would be capable of producing the same action. That iron is actually capable of causing corrosion I have proved by experiment. Pieces of brass sheet and tube were bound with iron wire and exposed to a current of hot sea-water for several weeks. In about two days the iron was completely oxidised, and distinct corrosion then became manifest upon the brass, resulting in the formation of an irregular groove in the metal along the line of the wire, a process that must have resulted in a hole if the experiment could have been continued long enough. The holes in the defective tubes extend, almost without exception, along the lower internal surface, upon which particles could collect. In one or two cases, out of a large number I have seen, in which the perforation was not confined to the lower side, it can easily be accounted for by supposing the offending particle to be cemented to the side by the earthy deposit which is thrown down continually from the water.

As to sheathing, I have already referred to the fact that the corrosion is most marked about the water line, a circumstance which is quite in conformity with the hypothesis that the action is mainly due to the incrustation.

4. Of course it is not maintained there may not be occasional instances of pitting arising from the existence of flaws in the metal. Undoubtedly this happens now and then, but I do not believe that it is a frequent cause. I was not prepared to find that bending of the metal would alter the rate of attack, but evidently this should be taken into account.

There are several practical lessons of importance which may be learnt from an inquiry into this subject. The chief of these I take to be the importance of keeping the surfaces of copper and alloy as clean as possible. In the case of condenser tubes I should imagine there would be no serious difficulty about clearing them out every time a vessel goes into port, and before they have time to dry inside by brushing out with a stiff brush. Locomotive boiler tubes are in different circumstances, and, moreover, the corrosion noticed in such case is not generally due so much to the salts in the water used as to the overheating and burning of portions of the tube, which became so thickly encrusted with calcareous deposit as not to be in contact with the water.

Another point is the desirability of avoiding distortion of the metal by bending, boring or otherwise. Holes for rivets should be punched or bored out quite clean without altering the form of the plate or tube. And lastly, contact with other metals should never be permitted in structures which are to be used in connection with sea-water or well waters containing large quantities of chlorides and other salts. Solder, whilst itself undergoing rapid destruction under such circumstances, exercises a protective influence. But copper should not be placed in contact with gun-metal, bronze or brass, as it will assuredly suffer.

Dr. Percy was good enough to show me lately an excellent example of the effect of such contact. A copper condenser tube, although quite round elsewhere, had become perforated close to the point of contact with a gun-metal dividing plate or partition.

Some of the tubes on the table show on the outside, near the ends, where they have been in contact with the condenser casing, the commencement of similar action.

In conclusion, I desire to say that I am fully conscious of many deficiencies and omissions in this attempt to explain these perplexing phenomena. I should like, for example, to include phosphor bronzes in my experiments, and this, perhaps, I may be tempted to do hereafter.

Finally, I desire to express my best thanks to those gentlemen who have kindly supplied me with specimens or material, especially to Messrs. Elliott, Heaton, Allen, Everitt & Sons, and to Mr. Clifford.

DISCUSSION.

Mr. F. MUNTZ asked for an explanation of the fact that ship sheathing was often so unequally worn that portions were full of holes, whilst the remainder was perfectly sound.

Mr. ROWLEY inquired as to the effect of tinning condenser tubes. He had found that in acetic acid tin was acted upon very slightly, whilst copper was strongly attacked.

Mr. ENOCH EVANS had understood Dr. Tilden to say that holes should be punched out, not drilled. Having been under the impression that it was better to bore the necessary holes than to punch them, he would be glad of information on that point. He thought the effect of impurities in the metal would account for some of the effects described in the paper.

Mr. DAWSON said he had seen ocean-going steamers with some of the tubes tinned inside, and these had gone much worse than copper. In some cases tinned tubes would stand, and in some cases they would not. He also knew of cases in which, on arriving in port, the greatest care had been taken to wash out the tubes with spring water, so that it was impossible that salt water could have been left lying in the tubes in the manner described in the paper. He was also of opinion that the presence of foreign particles imbedded in the substance of the tube was, in some cases, the cause of perforation.

Dr. TILDEN, in replying, referred the perforation of sheathing chiefly to the action of the green crust, which, from circumstances impossible to contest, was formed and adheres in patches. This was contrary to an opinion formerly current that the incrustation had a protective influence. He had also considered the question of tinning condenser tubes; but, although the surface was protected by a coating of tin as long as the latter was intact, yet directly the brass from any cause became exposed, the action of the sea-water was greatly increased.

With reference to the important question as to impurities in the shape of particles of carbon or of foreign metals imbedded in the brass, he had examined a great many samples of the metal with the object of detecting them, and had failed to find anything of the sort, except in one solitary instance in which a particle of iron was pressed into the surface of the tube. Many samples of metal had been treated with dilute nitric acid till almost dissolved away, and he had always found on examination at intervals that so long as the metal was completely immersed in the acid, and kept from contact with anything else, the sheets were thinned down uniformly, and exhibited all over the surface a finely

crystalline structure, and there was no inequality or localisation of the action.

As to the relative advantages of punching or drilling, he had no opinion to offer. All he meant to indicate was that the sheet or tube should not be bent or distorted in any way.

BUSINESS FOR NEXT MEETING.

March 2nd.—Professor Mills, D.Sc., F.R.S., "On Viscosity Determinations."

Mr. C. J. Ellis, F.C.S., "On Maumené's Test for Oils."
Mr. R. T. Thomson, "On the Determination of Oxide of Iron and Alumina in Commercial Phosphates."

Notices of papers and communications for the meetings to be sent to the Local Secretary.

The Fourth Meeting of the Session was held in the Rooms, 207, Bath Street, on Tuesday, 2nd February, 1886.

MR. J. NEILSON CUTHBERTSON IN THE CHAIR.

ACTION OF CHLORIDE OF SODIUM ON SOLUTIONS OF SOAPS.

BY T. N. WHITELAW.

In the methods most commonly employed to manufacture soaps, the action of sodium chloride on solutions of soap plays an important part. With small quantities of sodium chloride soaps may be rendered more liquid in the boiling operation, and by the addition of larger quantities the soap can be separated from excess of water and from impurities, while the prolonged boiling with salt solutions is often adopted to bring soap to a certain strength for special purposes, or to obtain a hard soap by thus withdrawing water from it.

It has been long well known that soaps are insoluble in solutions of salt of a certain strength, and that when boiled with such solutions the amount of water retained by the soap varies inversely as the quantity of NaCl in solution, but no experiments have been published defining this action.

I have endeavoured to contribute something towards a more definite knowledge of this matter. For this purpose I selected tallow and palm oil, the soaps from which behave differently with solutions of salt; the greater number of oils used in soap-making resembling tallow, while cocoa-nut oil is more like palm-nut oil in the manner in which its soap solution behaves with NaCl. Tallow and palm-nut oil soaps are therefore selected as affording types of the manner in which solutions of soaps behave with salt.

6grms. of fatty acids from tallow and palm-nut oils respectively, were saponified in a flask of about 250cc., separated with excess of caustic soda from solution, and after cooling until the soap curds had solidified, the caustic soda liquor was allowed to drain off.

The soaps obtained were dissolved in 100cc. of distilled water, and a weighed quantity of pure NaCl added, enough to obtain distinct separation of the soaps in small curds, then water was added in small quantities from a burette, and the soap solution brought to the boiling point and well agitated after each addition, a cork provided with about 14in. of glass tubing preventing any loss of water during the momentary boiling. Certain fairly well marked points were observed during the addition of water.

With a certain strength of solution the soap grains were distinct and separate, without any tendency to settle out fluid soap. With a further addition of water the grains became softer, and a thin layer of fluid soap could be observed settling beneath them. With the further addition of water the grains became entirely fluid, and the fluid soap occupied more and more of the total fluid volume as more water was added, until a point was reached when the fluid becomes clear and bright, and the soap completely dissolved. The points of distinct separation in grains, and the points of complete solubility in boiling solutions, are as follow:—

	Tallow Soap.	Palm-nut Oil Soap
Separates in distinct grains,		
NaCl per cent.	6.5	18.0
Clear hot solution (100° C.)		
NaCl per cent.	3.0	13.0

On slowly cooling those solutions, the tallow soap remained completely soluble, and when cold formed a firm jelly, while the palm nut oil soap separated as it cooled into a thin layer on the surface of the salt solution. It was found that tallow soap is nearly as soluble in the cold as in the hot solution of salt, but that while palm-nut oil soap is soluble in boiling water containing 13 per cent. of NaCl, it is insoluble in cold solution of 3 per cent.

It is important to notice the composition of the soap as it is separated in distinct grains from salt solution, and also when the grains, slightly liquefied, float on a thin layer of liquid soap above the salt solution. In the first case we have an ordinary soft curd soap, and in the second case, if we consider the subnatant salt solution removed, we have soap grains washed by a solution of soap, and both the method of purifying with salt and purifying with soap are adopted on a large scale to obtain pure soap of a definite composition.

The following are testings of soap thus settled from salt or curd soap; and soap settled from soap, or fitted soap:—

	Palm-oil Curd Soap.	Fitted Soap (Tallow, Resin).
H ₂ O	31.38	31.4
Na ₂ O	7.13	7.0
Fatty anhydride	59.82	60.3
NaCl	1.67	1.3
	100.0	100.0

To investigate the action of more concentrated solutions of chloride of sodium upon soaps, the same flask, with cork and tube to prevent loss by evaporation, was employed. The mixture of salt solution and soap grains was brought to the boiling point and well agitated from time to time, then this having been done for a definite time, the soap grains were quickly filtered from the salt solution through wire gauze, and spread like butter upon an ordinary towel of firm texture, then well pressed to remove water. By this means the soap was obtained with a varying amount of NaCl, but fairly free from mechanically mixed water.

A soap from a good quality of olive oil, such as is used for Turkey-red dyeing, when so treated for 30 minutes, with an 8 per cent. solution of salt, retained 31.6 per cent. of water, with a 17 per cent. solution it retained 25.7 per cent., and with a hot saturated solution it retained 19.1 per cent.

Underneath are analyses of various soaps after 30 minutes' treatment with a hot saturated solution of salt, and one of soap after 60 minutes' treatment, to find if more prolonged treatment tended to still further reduce the quantity of water retained by soaps. During this operation the soap grains become very small and hard, and when pressed between the folds of a towel they solidify at once, and are readily detached from it.

	Olive Soap. 30 min.	Olive Soap. 60 min.	Tallow Soap. 30 min.	Palm Nut. 30 min.
Fatty anhydride.....	67.9	67.38	64.49	66.4
Na ₂ O.....	7.8	7.75	7.64	9.9
H ₂ O.....	19.1	19.11	16.91	18.8
NaCl.....	5.2	5.16	10.93	4.9
	100.0	100.00	100.00	100.0

	Cotton Oil.	Castor.
Fatty anhydride.....	62.4	31.3
Na ₂ O.....	6.4	3.7
H ₂ O.....	17.2	48.3
NaCl.....	14.0	16.7
	100.0	100.0

The NaCl was obtained by difference.

It will be seen from the above that prolonged boiling did not reduce the quantity of water retained by the soap after 30 minutes' treatment. We have therefore here reached a limit to the action of sodium chloride in withdrawing water from soaps.

If we consider the chloride of sodium in the above analyses to be mechanically mixed with the soaps, we obtain by calculation the following percentage amounts of water in the hydrated soaps:—

	Soap.	Water.
Tallow Soap.....	80.9	19.1
Olive-oil Soap.....	79.8	20.2
Palm-nut Oil Soap.....	80.2	19.8
Cotton-oil Soap.....	80.0	20.0

Castor oil behaves differently from most other oils with solutions of salt; it is soluble in very concentrated solutions, and, as the above analyses shows, it retains a large quantity of water when treated with saturated solutions.

Viscosity of Soap Solutions.—I have also made some experiments to investigate the nature of solutions of various soaps, to determine with what quantities of water they tend to gelatinise, and what are their relative viscosities. The solutions of soaps exhibit important differences which afford indications as to their purity, and as it is in the state of solution that soaps are used, their nature in this state has a special interest. For most uses the value of soap depends largely on its quality of lubricating, of allowing a fabric to be rubbed with as little wear as possible, and in the operation of milling, where the aim is to cause the fabric to shrink by submitting it to pressure and rubbing, soap is employed chiefly as a lubricant, the goods being washed previous to the operation. For certain uses, therefore, it seems desirable to consider the differences of soap solutions in viscosity, as those differences are very marked, and small quantities of certain soaps may do the same work as large quantities of others.

Solutions of various strengths were made from soaps of the following oils, and after allowing those solutions to stand for 24 hours, an attempt was made to determine by observation the point at which the

solution ceased to form a jelly; the points determined were as follow:—

Green olive (sulpho-carbon).	1 in 18	water
Olive oil (old)	1 in 50	"
Cotton oil	1 in 100	"
Palm nut	150	"
1 resin, 3 tallow		
Tallow	200 to 250	"
Palm oil		"

This point was at any time rather difficult to determine, and tended to vary with the length of time the solutions were allowed to stand.

To compare the viscosity of the various solutions, a 50cc. pipette was used, from which water took 28.2 seconds to flow. The time of efflux for the soap solutions was then determined, having previously shaken them to destroy their gelatinous structure. Temperatures of solutions 50° F. The following points were noted:—

Soaps.	
Green olive oil (sulpho carbon)	1 in 50 water took under 30° secs.
Green	1 in 120 " " " 28.4 "
Cotton oil	1 in 320 " " " 30.4 "
Palm-nut oil	1 in 320 " " " 29.5 "
"	1 in 700 " " " 28.5 "
Pale soap	1 in 700 " " " 28.5 "
"	1 in 600 " " " 30.2 "
Tallow	1 in 700 " " " 29.5 "
Palm oil	1 in 700 " " " 29.5 "

The above list is sufficient to indicate that from this mode of testing soap solutions some light may be thrown on the nature of the fatty bodies from which soaps are made, and to suggest the propriety of selecting soaps for certain purposes according to the viscosity of their solutions.

DISCUSSION.

Prof. MILLS asked if Mr. Whitelaw had made any experiments with thickened rape oil and cotton oil, and whether soaps made from these separated out according to the same law as soaps from the other common oils?

Mr. HUTCHESON suggested that Mr. Whitelaw should make some experiments on the viscosity of soap solutions with fixed quantities of different soaps in varying quantities of water.

Mr. CHRISTIE asked if the author had given any attention to the relative melting points of the fats used for making his experimental soaps? According to his own observations, soaps made from fats containing oleine or oleic acid, were more difficult to salt out than those made from hard fats such as tallow. An intimate relation undoubtedly existed between the proportion of oleine in a soap and the quantity of salt required to throw it out of solution. Castor and cocoa-nut oils, consisting almost entirely of a fat resembling oleine in character and reactions, produced soaps most difficult to salt out. He thought that the results of the author's experiments on olive-oil soaps were not reliable, owing to the absence of any data as to the percentage of stearine in the olive oil. Judging from the results obtained, he should say that an Italian oil had been used containing far more stearine than Malta, Spanish, and Mogador olive oils did. Some of the latter formed soaps so difficult to salt out that one might almost class them with castor oil rather than with such olive oils as were used by the author. He was of opinion that soap solutions declined in viscosity as they contained less stearine, even though there was a corresponding increase in the amount of oleine present. He had used 10 per cent. solutions of oleine soap which would remain fluid for weeks at ordinary temperatures.

Mr. WHITELAW: I have not seen thickened rape and cotton oils, and have no experience of soaps

and anyone interested in its manufacture or uses should read an article in the *Mechanical World*, 25th March, 1885. If not desirous of making liquid carbon-dioxide, the gas could be compressed in suitable vessels to 100 or 200lb. per square inch, and it would, I am sure, find a ready market.

4. *Ammonia-soda Process.*—The CO_2 required in this process for the production of bicarbonate of ammonia is generally obtained by burning limestone in specially-constructed kilns. As only a 25 per cent. gas by volume can on an average be obtained, it necessitates extra pumping. A supply of CO_2 , such as could be got from the distilleries, would be of great value to a maker of this article, and it would almost constitute as great an advantage to be close to a good supply of it as to that of the rock-salt.

5. *Decomposition of Alkali-waste.*—In 1859, Mr. Gossage, and, in recent years, Messrs. Schaffner and Helbig, have taken out patents for the recovery of sulphur from alkali-waste, and which, at their respective times, were looked upon as valuable inventions. In both instances, what militated very much against the success of the process was the want of a good supply of CO_2 , as the reactions involved did not proceed smoothly with CO_2 made from coke. A supply of waste CO_2 from the distilleries would, if available, contribute much to their success.

In many processes wherein the CO_2 from the burning of limestone or coke is used, it would be very beneficial to be able to raise the per cent. of CO_2 to, say, 50 or 60 per cent., and this would not be a difficult matter if a supply of this waste CO_2 were available.

The processes for the manufacture of bicarbonate of soda, aerated waters, or liquid carbon dioxide could be undertaken by either the distiller or the chemical manufacturer, the others only by the latter.

No doubt many will think the supply would not be eligible for chemical manufacturers, as it would have to be conveyed to an inconvenient distance. In answer to this, I may state that the largest distilleries are, as a rule, in the large towns—*i.e.*, London, Glasgow, Liverpool, Edinburgh, Dublin, and Belfast—and contain chemical works close at hand. In Glasgow we have, situated close together, the Port Dundas and the Dundas Hill distilleries, and within 200 yards are two of the largest chemical works in the city. If we increase the distance only a little further, we embrace St. Rollox and a large number of other works. To any of these works it would not be difficult to convey the CO_2 , either through pipes or in tanks; and even supposing there was not a chemical work within convenient distance of a distillery, I contend that where there is a large supply of gas it would justify a manufacturer in erecting a work within such a distance. We have an analogous case in the tar distillers, who erect their works in close proximity to gasworks.

Another objection which some may advance, is that the supply of CO_2 would be intermittent. This is accounted for by the fact that the Inland Revenue authorities do not allow a distiller to conduct the mashing and fermentation at the same time as he is working the stills; and, as the latter operation lasts two days, there is no fermentation going on during this time, and consequently there could not be a supply of CO_2 .

I do not think this is a strong objection, as the gas could be stored and used as required, like ordinary coal-gas.

Quantities Available.—We come now to the most important factor in the above proposal—namely, the quantity of CO_2 which is available—1st, from a single distillery, and 2nd, from the total quantity of alcohol manufactured in Great Britain and in Ireland

—and I hope to convince the most sceptical that it certainly (in some cases) is sufficiently large to be of value to chemical manufacturers.

The weekly production of one distillery in Glasgow, and also in Edinburgh, in good times will average 50,000 gallons of proof spirits per week. This corresponds to a yield of 1,764,600 cubic feet of CO_2 at 0°C . and 760mm. Reducing this volume to weight, we have 216,600lb. or 96.6 tons. There are several other distilleries whose production falls little short of these just mentioned. Now, in the second case, the total production for Great Britain and Ireland in 1883 amounted to about 25,000,000 gallons of proof spirit, so we shall have to multiply our previous figures by 500, and it corresponds in weight to 48,300 tons of CO_2 per annum.

We shall now try to get some idea as to what the above quantities of CO_2 correspond to when worked up into materials mentioned previously.

We have mentioned that 96.6 tons are produced per week at one distillery; this would give weekly—

Bicarbonate of soda	368 tons, calculating 100%
Bicarbonate of ammonia ..	173 " " "
Alkali waste, Schaffner and Helbig	158 " " pure CaS
Alkali waste, Gossage	158 " "
Liquid CO_2	96 " "

As regards the amount of aerated water to which this quantity of gas corresponds, I should imagine it would supply all the makers in the United Kingdom. By multiplying these figures by 500, we get the yield for each of the above articles, corresponding to the total make of the three kingdoms per annum—

Bicarbonate of soda	181,000 tons.
Bicarbonate of Ammonia ..	86,000 "
Alkali waste, Schaffner and Helbig ..	79,000 "
Alkali waste, Gossage	79,000 "
Liquid CO_2	48,000 "

I think that the above figures clearly demonstrate that the waste CO_2 from one distillery is sufficient to keep a large work supplied.

We shall in the next place try to arrive at some idea as regards the money value of gas from one distillery.

To produce 96.6 tons of CO_2 from limestone and HCl , there would be required of the former 219 tons at 100 per cent.; of the latter 533 tons at 30 per cent.

Taking the limestone at 6s. per ton, we have	£65
Taking the HCl 30% at 2s. per cwt. ..	1066
Total for limestone and HCl	<u>£1131</u>

We shall not add to this the cost of labour, apparatus, etc.; but just take the sum as it stands—£1131—as the value of 96.6 tons of CO_2 made in the usual way. To err on the safe side, we shall divide this number by 4, and we get roughly £280 as the value of this quantity of gas per week; so in one year it should add £14,560 to the revenue of one concern. Taking the production of the three kingdoms, we have as the value of CO_2 wasted, £140,000 per annum.

Taking the cost of production from limestone and HCl , the CO_2 should in reality be almost as valuable as the alcohol produced.

The average cost of one gallon, or 9.19lb., of proof spirit=2s.; therefore 1.0lb.=2½d.

To produce 1lb. of CO_2 from limestone and HCl , there is required for raw material 1½d., and adding the usual charges for labour, plant, etc., it could not be sold at a profit under 2d. per lb.

In conclusion, I may say that the iron masters, in order to recover a mere trace of ammonia from their waste gases, have found it profitable to erect a most expensive plant, and one which requires a consider-

able amount of labour in its working, and is difficult to keep in order. There could be little difficulty to overcome in the recovery of the waste CO_2 compared with that of the ammonia, and the expense could not be nearly so great; but the profit should be considerably larger. It is a pity to see such a valuable by-product wasted, and it is to be hoped that before long some enterprising firm, either of distillers or chemical manufacturers, will be able to make use of it.

It is only by making the most of what we have that we shall be able to compete more favourably with foreign countries, and pass more comfortably through such serious depressions of trade as we have been experiencing for some time past.

DISCUSSION.

Professor DITTMAR said that Mr. Fawsitt's paper was very suggestive and worthy of closest attention. The "fermentation carbonic anhydride" was particularly valuable on account of its purity, and especially on account of the absence of those undefined substances which give the peculiar smell to carbonic anhydride prepared from limestone. The idea of using this fermentation carbonic anhydride was not absolutely new, for the pharmacentists on the Rhine used formerly to prepare their own bicarbonate of soda, and for this purpose they used carbonic anhydride prepared by fermentation of alcohol.

Professor MILLS said it would be very interesting to scrub the carbonic acid, from the different fermentation processes, through a scentless mineral oil, and examine the products as collected.

Mr. FAWSITT replied that he had not made this experiment. He did not claim novelty in the idea of using carbonic anhydride to prepare bicarbonate of soda; but it had never been done in this country as far as he knew.

Journal and Patent* Literature.

I.—GENERAL PLANT, APPARATUS, AND MACHINERY.

Improvements in Apparatus for Separating Substances of different Sizes or Specific Gravities. T. W. B. Mumford and R. Moodie, Victoria Docks. Eng. Pat. 1455, February 2, 1885. 8d.

THE apparatus, constructed according to this invention, consists of a casing, in which is enclosed a fan in proximity to a number of contracted passages formed by louvres, giving between them spaces inclined upwards towards the fan. When the fan is rotated, the currents of air so produced cause the separation of the finer from the coarser portions of matter fed into the apparatus. Series of receptacles or guides to receptacles are placed beneath the passages.—E. G. C.

Improvements in Centrifugal Machines for Drying Sugar and other Crystalline or Granular Substances. G. Fletcher, Litchurch; and W. P. Abell, Kirby Lodge. Eng. Pat. 1540, February 5, 1885. 8d.

IN centrifugal drying machines the inventors provide a

* Any of these specifications may be obtained by post, by remitting the cost price, plus postage, to Mr. H. Reader Laek, Comptroller of the Patent Office, Southampton Buildings, Chancery Lane, London, W.C. The amount of postage may be calculated as follows:—

If the price does not exceed 8d.	4d.
Above 8d., and not exceeding 1s. 6d. ...	1d.
" 1s. 6d., " " " 2s. 4d. ...	1d.
" 2s. 4d., " " " 3s. 4d. ...	2d.

horizontal revolving disc, the upper surface of which is fitted with spiral arms reaching from near the centre to the periphery. These arms, which revolve in a direction coinciding with that of the spiral curve, are made of gauze, and have secondary solid spiral arms or shields behind them, forming channels or boxes, into which the liquid runs as it is driven through the gauze surface, and is thence, by means of suitable spouts, discharged into a circular trough. The solid material passes along the surface of the gauze arms until it is thrown off at the outer point, and is collected in the casing.—B.

Improvements in Apparatus for Distributing or Spreading Liquids over Surfaces. C. F. Claus, South Wimbledon. Eng. Pat. 585, January 15, 1885. 8d.

THE inventor distributes a liquid uniformly in small quantities over a large surface, by means of a number of small intermittent syphons or luted pipes, fixed in the bottom plate of a tank which is placed over and covers the whole surface to be moistened. The tank is fed inter-

mittently, preferably by means of either a large intermittent syphon, or of a tumbling box, supplying at each discharge a larger quantity of liquid than all the smaller syphons together can pass in the same interval of time. The sketch represents one of the arrangements of small sealed pipes.—B.

An Improved Pyrometer. J. Frew, Lanarkshire. Eng. Pat. 2568, February 25, 1885. 8d.

A BLAST of air, at approximately uniform temperature and pressure, is led by a tube through a small orifice in a tubular worm or other hollow vessel, placed within the hot blast pipe. The air is allowed to escape from the worm by an outlet orifice, constructed so as to be of smaller size than the inlet, a uniform pressure rather higher than the atmospheric pressure thus being maintained within the worm. The worm communicates with a vessel containing a coloured liquid, and provided with a vertical glass tube in which the liquid rises, in consequence of the expansion of the air within the worm, caused by the heat communicated by the hot blast. Uniform pressure of the cold blast passing to the worm may be obtained by the use of a pressure-reducing valve, or by dipping a branch from the cold blast inlet-pipe into water kept at an uniform level.—E. G. C.

Preventing the Formation of Scale in Boilers, Heaters, and other Apparatus, and removing Scale therefrom.

H. Aitken, Falkirk. Eng. Pat. 2662, February 27, 1885. 8d.

THE inventor places in the boiler series of zinc and copper plates, disposed in alternate layers. For the zinc he may substitute iron, and for the copper, carbon, silver or platinum.—B.

Improved Method of ascertaining the Specific Gravity, the Pressure, and the Component Parts of Fluids. Friedrich Lux, Ludwigshafen. Eng. Pat. 13,050, October 29, 1885. Sd.

A CLOSED weighing vessel is supported by one arm of the balance lever, and connected with conduits partaking of the oscillating motion of the beam. These conduits convey the fluid to be weighed into and out of the weighing vessel, the specific gravity, weight or pressure of the fluid being indicated continuously, so as to be read off a graduated scale connected with the balance.—E. G. C.

II.—FUEL, GAS, AND LIGHT.

Improvements in Apparatus for Generating Gas. Henry Hutchinson, London. Eng. Pat. 132, October 3, 1885. Sd.

THIS invention is an improvement upon that described in Eng. Pat. 2843, of 1883, according to which, gas is generated from carbonaceous matter in a retort by the action of the heat produced within the apparatus by the combustion of a portion of the carbonaceous material itself. An ordinary brick-lined generator is provided with a central structure, consisting of three concentric tubes. The innermost one, communicating at the top with the interior of the generator, and at the bottom with a gas main, is for carrying off the gases as they are evolved. The annular space between the innermost and the intermediate tubes is for the reception of liquid hydrocarbon, which is vaporised by the heat of the escaping gases, and passes by suitable openings into the body of the generator, mingling with and enriching the other gases evolved there. The outer tube is intended for heating the air used in the process, and also communicates by a number of openings with the interior of the furnace. This air is forced into the apparatus by a steam jet, and may, if desired, be mixed with hydrocarbon vapour. For further details of the plant, the original specification with its drawings must be consulted.—A. R. D.

Improvements in the Method of, and Apparatus for, Purifying Coal Gas. Jno. Hanson, Bingley. Eng. Pat. 1026, October 22, 1885. Sd.

THE gas is passed through a long casing of metal plates, inside which are two agitators working in opposite directions. These agitators are of cylindrical form, and packed with iron bars in such a way as to present an irregular kind of mesh for the passage of the gas. The iron casing is filled to a certain height with a mixture of ammoniacal liquor and oxide of iron; and the gas impinging upon this, as it adheres to the agitators, has the sulphur compounds eliminated. The liquor is revived by running the apparatus without passing gas through it.—A. R. D.

III.—DESTRUCTIVE DISTILLATION, TAR PRODUCTS, Etc.

Presence of 1:2:4:5 Durene in Coal Tar. K. E. Schulze. Ber. 18, 3032—3034.

THIS hydrocarbon was isolated from that portion of coal-tar boiling between 170° and 210°. After removing all basic and phenolic substances, the residual oil was subjected to fractional treatment with sulphuric acid of various degrees of concentration. The sulphonic acids thus obtained were then hydrolysed according to the method described by Armstrong and Miller (this Journal 3, 371). The first treatment of the oil was effected with dilute sulphuric acid containing 66 per cent. of H₂SO₄; the strength of the acid was gradually increased to from 75 to 95 per cent., and finally the oil was digested with fuming sulphuric acid containing from 5 to 50 per cent. of SO₃. On subjecting the last fraction to hydrolysis, a distillate was obtained, yielding a crystalline deposit on cooling. The latter was filtered off, pressed strongly,

and recrystallised from alcohol. Analysis gave numbers agreeing with the formula C₁₀H₁₄. The properties of this hydrocarbon are as follows:—White laminae exhibiting a faint fluorescence. Compared with naphthalene, its power of subliming is very slight. It has a faint odour similar to pseudocumene, melts at 80—81°, and boils at 196°. This hydrocarbon is therefore identical with the symmetrical durene obtained from xylene and pseudocumene by means of Fittig's synthesis.

—D. B.

Anthrapinacone, a New Reduction Product of Anthraquinone. K. E. Schulze. Ber. 18, 3034—3036.

HAVING occasion to prepare chemically pure anthracene according to Perger's method, involving the reduction of anthraquinone to dihydroxyanthranol, and the decomposition of the latter into anthracene and water, the small yield (only 40 per cent. of the theoretical) induced the author to investigate the other compounds formed in the reaction. The organic matter was extracted from the zinc dust by repeated treatment with petroleum spirit as suggested by Perger. On treating the residual zinc dust with xylene, a further extract was obtained, which, on cooling, gave a crystalline deposit resembling dihydroxyanthranol in appearance, but differing from it by its greater insolubility in alcohol. The deposit was purified by recrystallisation from boiling benzene, toluene or xylene, white needles being obtained. On analysis, it gave numbers corresponding with the formula C₁₄H₁₂O. Hence it is a pinacone of anthracene. Anthrapinacone has a melting-point of 182°. When heated to 100° in a sealed tube with acetyl chloride dianthranyl (C₁₄H₈)₂ is formed. It crystallises in yellow laminae, melting at 300°.—D. B.

β-Hydroxyanthranol, a New Oxidation Product of Anthracene. K. E. Schulze. Ber. 18, 3036—3039.

CONSIDERATIONS on the constitution of anthraquinone and phthalylechloride made it desirable to investigate the progress of the oxidation of anthracene into anthraquinone. A series of oxidation experiments was instituted, the object being to find an oxidising agent which would admit of interrupting the oxidation before any anthraquinone is formed. Lead peroxide was found to give the best results, a compound being formed which resembled hydroxyanthranol in most of its properties, but differed in its behaviour with an alkaline solution of copper sulphate. The new substance separated cuprous oxide, and gave a black colour to the solution, whilst hydroxyanthranol merely decolourised the solution. Owing to the great instability of the compound, it could not be analysed by combustion. From the constitution of its ethyl derivative, prepared by boiling the substance with an alcoholic solution of potash and ethyl iodide, its formula appears to be C₁₄H₁₀O₂. Its constitution may be represented thus:—

The ethyl derivative forms yellow transparent rhombic crystals, the methyl compound crystallises in yellow transparent plates melting at 196°, whilst the benzyl derivative forms tough vitreous, almost colourless crystals, melting at 220°.—D. B.

On β-Picoline and the Synthesis of some Homologues of Pyridine. A. Heseckel. Ber. 18, 3091—3100.

THE author has prepared β-picoline, according to Zanon's method, from acetamide, glycerol and phosphoric anhydride. It boils at 141·5—143·5°, has a sp. gr. of 0·977 at 0°, and gives on analysis numbers corresponding to the formula C₈H₇N. The mercuriochloride forms fine white needles soluble in water and melting at 143°; the aurochloride is a yellow compound sparingly soluble in water, and melts at 182—184°; the picrate forms shining needles which are soluble in water and

alcohol, and melt at 145–146°. The zincchloride crystallises in white lustrous needles, sparingly soluble in water, and melting at 158°. The platinumchloride forms orange needles, melting at 214°.

The author has prepared *ethylmethylpyridine* $C_8H_{11}N$ from paraldehyde, acetamide, and phosphoric anhydride. It forms a clear colourless oil resembling collidine in odour, and boils at 175–179°. The platinumchloride, melting at 180°, forms rhombic orange plates; the aurichloride crystallises from water in yellow needles melting at 72°; and the picrate forms greenish yellow rhombic (?) plates melting at 175°.

Parvaline C_8H_9N was prepared by heating a mixture of propionic aldehyde, acetamide, and phosphoric anhydride to 190° for 48 hours. From the product of the reaction a colourless oil was isolated, which boiled at 196–200°. The platinumchloride crystallises in small needles, and the picrate in large yellow plates.—D. B.

IV.—COLOURING MATTERS AND DYES.

Improvements in the Production of Azo-colours on Textile Fibre. Thomas Holliday. Eng. Pat. 2580, February 25, 1885. 6d.

THE object of this invention is to produce in the fibre mixed azo-compounds derived from monamines, such as aniline and its homologues, the naphthylamines, amido-azo-benzene, etc., and the azo-derivatives of the rosaniline colouring matters. As an example of the mode of application, the inventor gives the following:—Naphthylamine and rosaniline are dissolved together by means of dilute hydrochloric acid, and diazotised in the usual way. The fabric is first immersed in a solution of naphthol after which the excess of liquor is wrung out, and then it is transferred to the solution of the mixed diazo-chlorides, when the colour is at once developed. Other modes of application are described in the patent.—R. M.

A Manufacture of Blue and Violet Colouring Matters. Herbert John Haddan, 67, Strand. From the "Farbenfabriken vorm. F. Bayer & Co.," Elberfeld. Eng. Pat. 3449, March 10, 1885. 6d.

THE colouring matters in question are produced by the action of Rathke's "perchloromethyl-mercaptan" (resulting from the action of Cl upon CS_2) upon tertiary monamines. The process is illustrated by the manufacture of a colouring matter from dimethylaniline, twenty-five parts of this base being mixed with eight parts of calcium carbonate in a vessel provided with a stirrer, eleven parts of the mercaptan being run into the cold mixture. The temperature is then raised to 80° C. by means of a water-bath, and kept thus for twenty-four hours, when a coppery melt is obtained, from which the crystallisable colouring matter can be extracted by means of water after the removal of the excess of dimethylaniline by steam distillation. The colour-base is converted into one of its salts for the market.—R. M.

Colouring Matters obtainable by the Combination of Tetrazoditolyl or Tetrazodicycyl Salts with Alpha- and Beta-naphthylamine or their Mono- and Disulphonic Acids, and Process for the Manufacture of the same. Herbert John Haddan, 67, Strand. From the "Farbenfabriken vorm. F. Bayer & Co.," Elberfeld. Eng. Pat. 3803, March 14, 1885. 4d.

THE diamidoditolyl and diamidodicycyl required are prepared from nitrotoluenes and nitroxylenes according to the method of G. Schultz (*Ber.* xvii, 467 and 472), and these are diazotised in the usual way. The tetrazo-salts are made to act upon solutions of the salts of the naphthylamines either in aqueous or alcoholic solutions, and the resulting insoluble azo-colours converted into sulphonic acids. If the sulphonic acids of the naphthylamines are employed, alkaline solutions of their salts must be made use of, and the resulting azo-colours are soluble. Particularly fine colouring matters are said to be obtained by the action of the tetrazo-chlorides upon

the β -naphthylaminesulphonic acid obtained by the action of NH_3 upon Schäffer's β -naphthol-monosulphonic acid and upon the β -naphthylaminesulphonic acid, formed by heating β -naphthylamine with strong H_2SO_4 to 200–210° C. These tetrazo colours are said to be much more soluble, and to be less sensitive to acids than the corresponding benzidine colours; they have the property of dyeing unmoordanted cotton in an alkaline bath.

—R. M.

Improvements in the Manufacture of Azo Dyestuffs or Colouring Matters. Emil Elsaesser, Brogler Strasse, Barmen, Prussia. Eng. Pat. 14,232, November 20, 1885. 4d.

THE colouring matters forming the subject of this patent are produced by the action of the diazo-salts of Merz and Weith's thioparatoluidine (*Ber.* vol. iv, p. 393) upon the sulphonic acids of the naphthols and naphthylamines. In order to prepare thioparatoluidine, eleven kilos. of sulphur are dissolved in forty kilos. melted paratoluidine, heated to 150° C. in an iron vessel, and forty-two kilos. of litharge are gradually added till the further addition of this substance no longer produces an effervescence. The excess of toluidine is removed by steam distillation, and the thio-base extracted by means of dilute hydrochloric acid, and precipitated by means of an alkali. By acting upon the hydrochloride of the thio-base with nitrous acid, tetrazothioparatoluidene-chloride is produced, and this can be combined with the naphtholsulphonic acids, etc., in the usual manner. As an example, the inventor gives the process for making the red dyestuffs resulting from the action of the tetrazo-salt upon the theoretical quantity (two molecules) of β -naphtholdisulphonic acid, or of Piria's naphthionic acid.—R. M.

V.—TEXTILES: COTTON, WOOL, SILK, Etc.

Improvements in Means for Rendering Fabrics and other Substances Uninflamable, Obnoxious to Vermin, Resistant to Putrefaction, to the Reception of Morbid or Diseased Matter, and to the Growth of Spores, Fungi, Bacteria, and the like. W. L. Wise. From Josef Ferdinand Notz. Eng. Pat. 1232, January 28, 1885. 6d.

THE inventor claims for the above purposes the use of a liquid containing sulphate of ammonia, carbonate of ammonia, borax, bichloride of mercury, peppermint, carbolic acid, bi-tungstate of soda, and chloride of lime, transformed into an emulsion by leading into the solution the products obtained from the distillation of a solution of Peruvian balsam and camphor.—E. J. B.

An Improved Means and Method of Making Woven and Felted Fabrics, Cardboard, and Wood Waterproof and Acid Proof. H. Sharp. Eng. Pat. 2534, February 25, 1885. 6d.

THE material to be rendered waterproof is thoroughly dried by being heated in vacuo, and whilst still hot is saturated with melted paraffin wax containing a small proportion of liquid paraffin. When cold it is passed between hot rollers so as to spread the wax more evenly, and is finally passed through cold calender rollers, to which a heavy pressure is applied. For certain purposes the fabric may be previously prepared by soaking in a solution of gelatine, containing one-fifth of its weight of bichromate of potash.—E. J. B.

Improvements in the Method of, and Machinery for, Washing or Scouring Wool. W. Cook. Eng. Pat. 4028, 1885. 8d.

THE wool is carried forward on an endless belt of wire gauze through a series of troughs, in which water is caused to flow at the same speed by means of paddles. In its passage through the troughs, the wool is occasionally squeezed by perforated drums. Complete drawings accompany the specification.—E. J. B.

A New or Improved Apparatus for Washing Wool by a Continuous Stream of Water, and also for Purifying such Water. A. Deletombe and A. Prouvest. Eng. Pat. 4586, 1885. 11d.

By this method the wool passes through a series of tanks placed at different heights. After undergoing a certain amount of cleansing in the top tank, it is raised by means of paddles, and transferred to the next lowest tank. In passing from one tank to another, the wool is squeezed by means of rollers. The proper amount of soap solution is supplied regularly by means of a patent apparatus (Mehil's patent). The dirty water from the tank is filtered through a cloth bag, and is transferred to a large vessel, where it is decomposed by an acid, and the fatty matters recovered. The water then undergoes a further process of settling and filtration; it may then be used for washing out the tanks. The inventor claims a considerable economy of soap by the use of the apparatus. —E. J. B.

VI.—DYEING, CALICO PRINTING, PAPER STAINING, AND BLEACHING.

On the Fixation of Aniline Dyes with Antimony Compounds. Chem. Zeit. 1710, 1885.

LAUBER and Schweikert made a large number of experiments in order to investigate the action of tartar emetic and antimony oxalate in the fixation of aniline dye tannates on the fibre. The authors came to the following conclusions:—(1) There is no material difference between equal weights of tartar emetic and antimony oxalate as regards the fixation of aniline dye tannates, although the oxalate contains less antimony. The use of the latter is therefore recommended on account of the considerable saving in money. (2) Mixtures of chalk and antimony salts act better than antimony solutions alone. (3) Basic antimony compounds, or antimony hydrate respectively, have no action in fixing aniline dyes.—S. H.

Improvement in the Preparation of the Sensitive Paper or other Fabrics applicable as a Substitute for Glass in Photography. L. Warnerke. Eng. Pat. 2699, 2d.

IN this invention, paper or other transparent or semi-transparent tissue is rendered sensitive to light on both sides. The light passes through the paper, which on development gives an image on both sides. Greater brilliancy and softness are produced in the prints from the negative obtained with such a paper.—E. J. B.

Improvements in the Means or Apparatus employed for Dyeing Woollen, Silk, and other Woven or Felted Fabrics and Yarns. Joseph Rellitt. Eng. Pat. 6295, May 22, 1885. 6d.

THE material to be dyed is passed through a small trough containing the dye, and is then passed over cylinders heated by steam. In this way considerable amounts, both of fuel and colouring matter, are saved. —E. J. B.

VII.—ACIDS, ALKALIS, AND SALTS.

On Pyrites. William Martyn. Abstract from "Mineral Resources of the United States, calendar years 1883 and 1884."—Department of the Interior, United States Geological Survey.

OCCURRENCE IN THE UNITED STATES.

New Hampshire.—From this State comes an excellent ore admirably adapted for acid making, and comparing favourably with the best Spanish ores. It is mined at Milan, in Coos county. The vein is 15 to 25 feet wide. There are also large quantities of ore containing a fair percentage of copper and silver, which are smelted at the mine, the copper matte being shipped to New York to be refined. The composition of Milan ore No. 1 is about

as follows:—Sulphur, 48.0 per cent.; iron, 43.0; copper, 1.6; zinc, 1.5; silica, 5.0; arsenic, traces; total, 99.1 per cent. The ore burns readily without clinkering, and requires very little attention to insure thorough desulphurisation. Milan ore No. 2 contains less sulphur and more zinc (up to 11 per cent.) than the above, which latter metal prevents the recovery of a fair proportion of sulphur owing to the formation of zinc sulphate. The mine is owned by the Milan Mining Co., of Boston, which supplies the ore broken to size, and screened ready for charging into the kiln.

Vermont.—At the Ely mine large quantities of low grade pyrites are found, but owing to its low percentage of sulphur, it has thus far not been used for acid making.

Massachusetts.—In the town of Rowe, Franklin County, is the Davis mine, at which work was commenced in 1882. The vein material is almost pure iron pyrites with a slight admixture of copper pyrites and quartz. The ore, which is distinctly crystalline, has the following composition:—Sulphur, 48.0 per cent.; iron, 44.0; copper, 1.6; zinc, lead, etc., 1.5; silica, 3.7; arsenic 0.2; total, 98.8 per cent. The "smalls" are remarkably pure, containing upwards of 48 per cent. of sulphur, and can be readily roasted down in shelf burners to 3 per cent. sulphur. A large quantity of Davis ore has been burned during the last few years, and it is in favour with manufacturers owing to the absence of arsenic. This, while of no great moment so far as the application of the greater portion of the acid is concerned, may yet be an important matter as regards the wear and tear of the chamber lead.

New York.—There are mines in Saint Lawrence County, near De Kalb. The ore contains 38 to 40 per cent. sulphur, and 2.75 per cent. copper. Some of it is said to contain a considerable percentage of silver. The ore is shipped to Canada and to Detroit.

Virginia.—The rich Virginian ore has a good place in the market. The following analysis of it is by Dr. Völkner, of London:—Sulphur, 48.02 per cent.; iron, 42.01; peroxide of iron, 1.93; sulphuric acid, 0.44; silica, 7.60; copper, none; arsenic, none; total, 100.00. Other analyses show from 46 to 50 per cent. sulphur. Lately the percentage of copper has increased, and in this way the value of the ore has risen. Three mines have been worked in Louisa county belonging to the Arminius Copper Mines Co., the Sulphur Mines Co. of Virginia, and Messrs. Charles Lenning and Boyd Smith respectively.

Georgia.—The pyrites raised at two mines in this State have been used for acid making. The mine of the Tallapoosa Copper Production Co. is in Haralson County, and that of the Paulding County Mining Co. is in Paulding County. Some of the ore contains as much as 11 per cent. copper, but the average is very much lower. The ore tests about:—Sulphur, 40.00; copper, 2.75; and silica, 8.00 per cent.

Deposits not now Worked.—There is scarcely a State in the Union in which pyrites does not occur to a considerable extent, and at the present time sulphuric acid makers can be cheaply supplied from the mines already opened. Many more of the existing deposits not now worked will doubtless be drawn upon as new acid making centres spring up.

FOREIGN DEPOSITS.

Canada.—The ore from Canadian deposits was the first to be used in the United States for making oil of vitriol. The Canadian pyrites are now supplied by the Albert mine, belonging to Messrs. G. H. Nichols & Co., of New York, and the Crown Mine, owned by the Orford Copper and Sulphur Co. The ore is very compact, and forms very little "smalls" on breaking. It burns well in the kilns, in which the charge may be 25 per cent. larger than with Spanish 48 per cent. ore. Its composition is about as follows:—Sulphur, 40.0; iron, 35.0; copper, 4.0; silica, 20.0 per cent.; arsenic, traces; and silver, 40zs. per ton. The cinders which were formerly smelted are now treated by the wet process for both copper and silver. Details on the deposits of pyrites in Spain, Portugal, France, and Germany are then stated, which

have been published so very frequently as to need no further mention in this abstract.

Domestic Production.—The production of pyrites in the United States during the last three years is given approximately below:—

Years.	Tons of 2,240 lb.	Spot Value.
1882	12,000	72,000 dollars.
1883	25,000	137,000 ..
1884	35,000	175,000 ..

The amount of capital in pyrites mining is probably about 200,000 dollars, and the number of men employed in 1884 was 175.

in many cases. Indeed, at the present time, none of the three great Spanish pyrites companies show any inclination to cultivate the American trade. A reduced consumption of pyrites in Europe by the introduction of any sulphur recovery or the ammonia-soda process, will probably result in the Spanish companies endeavouring to compensate themselves for the loss of European business by shipping at first large quantities of non-euphriferous ore to the United States. When the volume of business there becomes large enough, they will probably make extensive arrangements for treating the cinders and begin to ship euphriferous ore there, unless indeed they can make more profit by treating the ore for copper

IMPORTS OF PYRITES INTO THE UNITED STATES FROM 1880 TO 1881 INCLUSIVE.

Fiscal Years ending June 30.	CANADIAN.				NEWFOUND- LAND.		SPANISH.	TOTAL.
	Tons.	Copper.*		Value. dollars.	Duty. dollars.	Tons.	Tons.	Tons.
		per cent	lbs.					
1880	1,958	—	1,125,296	156,834	33,758	—	—	—
1881	10,812	4.0	982,809	102,543	29,786	—	1,115	11,927
1882	23,980	3.0	1,591,811	160,473	47,754	—	5,838	29,818
1883	25,211	2.5	1,403,900	131,400	39,879	—	10,600 †	35,811
1884 ‡	26,000	3.7	2,151,800	—	—	2,600	16,250	41,250

* The figures represent "dry assays"—1.30 per cent. less than actual (wet) assays. The Spanish ore imported has contained an average of only 1.25 per cent. copper (wet assay). Newfoundland ore contained about 3 per cent. wet assay.

† Spanish pyrites includes 1473 tons Portuguese (Mason and Barry) in 1883. The balance is almost all Rio Tinto ore.

‡ All the figures for 1884 are estimated, as also is the quantity of Spanish ore for 1883. This has been rendered necessary by the practice of some of the custom houses not to keep pyrites separate from iron ores.

Works burning Pyrites.—There are at present 23 establishments in the United States burning pyrites. They are located as follows:—Boston and eastern district, 5; New York district, 9; Philadelphia district, 2; Baltimore district (including South Carolina and Georgia) 3; western district, 4; total, 23. Two of the works use Canadian ore, four Spanish ore only, two Spanish and domestic, and fifteen domestic ore only. Nine of these establishments use grate burners only, nine grate and shelf burners, two shelf burners only, and three use the Spence mechanical furnace. The acid made at ten of the works is used for fertilisers, at three for oil refining, and at ten for miscellaneous purposes.

Terms on which the Ore is purchased.—The ore is usually bought under guarantee that it shall contain not less than an agreed percentage of sulphur, and that there shall not be more than a certain proportion of "smalls," say 7.5 per cent., through a $\frac{1}{4}$ inch mesh screen. Sometimes it is stipulated that the amount of zinc shall not exceed, say 2 per cent. The cinders are either given to the buyer, or are removed at the expense of the seller. After stating the manner of sampling and testing the ore for sulphur, some statistics on the pyrites consumption in the United States, England, France, Germany and Belgium are given, whence it must be concluded that the total quantity of pyrites used throughout the world for oil of vitriol making cannot be less than one million tons per year. The different kilns and burners for roasting lump ore and "smalls" are then described, as well as the Henderson wet copper process in combination with Claudet's silver process.

Competition of Foreign and Domestic Ores.—Although the Spanish pyrites practically control the whole pyrites trade of the Old World, it is probable that the domestic ore will be able for the present to hold its own side by side with Spanish ore in the American market. On the whole, the mines are near to manufacturing centres, the percentage of sulphur in the ore is high, copper and silver are present in suitable quantity, and it is comparatively free from zinc, lead, lime, etc.; whereas the absence of arsenic makes it preferable to Spanish ore

at the mines in Spain. This last supposition seems extremely unlikely. The cost of treating a 3 per cent. ore for copper at the mines is probably in no case less than 2 dollars per ton. If the same ore were shipped to the United States, the debits and credits would stand about as follow:—

DEBITS.	
Freight to Huelva	0.50 dollars.
Duty 75 cents per ton, plus 10 per cent. of 25 per cent. per lb. on 1 per cent. copper	0.80 ..
Ocean freight, etc.	2.75 ..
Treatment of cinder	4.90 ..
Balance in favour of shipping to the United States	1.65 ..
	10.60
CREDITS.	
Sulphur (say)	5.75 dollars.
Purple ore (3 dollars per ton)	2.10 ..
Silver	0.75 ..
	8.60 ..
Add cost of treatment at mine	2.00 ..
	10.60 ..

Time will show whether these apprehensions of extensive foreign competition with domestic ores are warranted or not.

Comparison of Pyrites and Brimstone.—In conclusion, there is a comparison between the cost of acid made from pyrites and brimstone. In such a calculation it must be kept in view that the cost of burners for pyrites is twice as much as for brimstone. On a ton of pyrites acid of 50° B. (106° Tw.) there is a charge of 35 cents for labour, whereas on a ton of brimstone acid of equal strength the cost for labour is only 27 cents. The wear and tear of chambers is between 20 and 30 per cent. greater with pyrites than with brimstone. On the other hand, the selling price of brimstone at the close of 1884 was about 23 dollars per ton, whereas the same available amount of sulphur in pyrites costs very considerably less, and there can therefore be no doubt that acid can be made from pyrites much cheaper than from brimstone.—S. H.

Material for "Packing" Glover Towers. Chem. Zeit. 1695, 1885.

THE "Rheinische Industrie für feuerfeste Produkte, Bendorf-am-Rhein," now makes clay tubes 12cm. or 15cm. long by 10cm. diameter, which are used in the place of flint for Glover towers. In this manner a far greater available surface is obtained, and owing to the small weight of these tubes, the structure need not be so strong.—S. H.

Manufacture of Zinc Chloride. Chem. Zeit. 1905, 1885.

SCRAP zinc placed in a stone, cast-iron, or wooden vessel, is dissolved in hydrochloric acid. The solution is neutralised with sodium carbonate warmed from 40° to 50° C., and a little bleaching powder added to precipitate iron and manganese. The clear zinc chloride solution is siphoned off and boiled down in enamelled iron pots. The evaporation is continued until the liquor shows a heat of 230 to 240° C., a little potassium chlorate is added to oxidise any organic matter, and some pure hydrochloric acid carefully poured into the hot solution in order to dissolve any basic salt. The mass is then allowed to solidify, the agitation being kept up all the time, and while still warm packed in iron drums of 30kgms. to 50kgms. capacity, which are at once closed air-tight.—S. H.

Improvements in the Treatment of Sulphides in Alkaline Solutions by Electrolysis. H. W. Deacon, F. Hurter, Widnes, and W. Elmore, Surrey. Eng. Pat. 800, January 20, 1885.

A CURRENT of electricity is passed through solutions containing alkaline sulphides, so that the sulphides contained in the said solutions may be decomposed by the current in such a manner that the sulphur is deposited upon the anode, hydrogen being evolved at the cathode; or that a portion or practically all of the sulphur is oxidised at the anode, hydrogen being evolved at the cathode. The alkali metal of the alkaline sulphide is thus obtained, either in form of caustic alkali, or as an alkaline sulphate. A convenient mode of removing the sulphur from the anode is effected by causing the anode to travel continually by mechanical means into and through the solution, and afterwards to pass by a scrubber or brush, which removes the sulphur and discharges it into a suitable receptacle.

Improvements in the Manufacture of Sulphur from Sulphuretted Hydrogen and Sulphurous Acid, or a Salt thereof. J. W. Kynaston, Liverpool. Eng. Pat. 2473, February 24, 1885. 6d.

IT is proposed to carry out the mutual reaction of sulphuretted hydrogen on sulphur dioxide in a new manner. Calcium or magnesium sulphite suspended in water is pumped into a flagstone still, provided with a wooden agitator. The latter is caused slowly to revolve, and then a current of sulphuretted hydrogen is forced in through a leaden pipe reaching to the bottom of the still. After a few minutes, or as soon as the mixture in the still is saturated with the gas, dilute hydrochloric acid (8 to 10° Tw.) is run in, and so regulated that for every two equivalents of sulphuretted hydrogen passing in, two equivalents of hydrochloric acid are added. The decomposition takes place according to the equation:— $\text{CaSO}_3 + 2\text{HCl} + 2\text{H}_2\text{S} = \text{CaCl}_2 + 3\text{S} + 3\text{H}_2\text{O}$. The batch is then run off to a filter bed, where the sulphur, which is in a pulverulent condition, is retained. The hydrochloric acid used must be perfectly cold, the success of the process depending greatly upon the temperature being kept as low as possible throughout. It is contended that by this mode of proceeding the formation of thionic acids and a consequent loss of sulphur can be completely avoided.

—S. H.

Improvements in Decomposing Liquors containing Chloride of Magnesium. J. Wilson, Berwick-on-Tweed. Eng. Pat. 3098, March 10, 1885. 6d.

THE liquor to be decomposed is evaporated till the liquid has a temperature of 300° F., or until a sample on cooling solidifies well. This concentrated solution is then run in a constant stream into a furnace, where it is mixed with a suitable absorbing agent; and the resulting solid mass is heated until it is sufficiently decomposed. It is proposed to use as absorbing agent the product of the decomposition of the concentrated liquor of a former operation. These steps are taken with a view of preventing the fusion of the mass, and the consequent destruction of the furnace bed.—S. H.

Improvements in the Manufacture of Potassium Sulphites. A. Boake and F. Roberts, London. Eng. Pat. 5882, May 13, 1885. 4d.

THIS invention consists in the manufacture of a new bisulphite of potassium, to which the name of isohydro-bisulphite of potassium has been given. Potassium bicarbonate or a mixture of potassium sulphate and calcium hydrate are treated at a boiling temperature with sulphurous acid, until the whole base is converted into bisulphite. The solution is allowed to crystallise, the mother-liquor being again treated with more base and sulphurous acid.—S. H.

Improvements in the Production of Sulphurous Acid for the Manufacture of the Sulphites and Bisulphites of the Alkalis and Alkaline Earths. P. Hart, Manchester. Eng. Pat. 13,950, November 16, 1885. 4d.

SULPHUR dioxide in a practically pure state is obtained by acting with strong sulphuric acid upon any of the sulphides, such as the sulphides of iron, copper, lead, tin, antimony, zinc, arsenic, etc. In practice, finely ground iron pyrites are placed in a cast-iron retort, and mixed with sulphuric acid of 1·750 sp. gr. Heat is then applied, and when the temperature has reached 400° F., a steady stream of nearly pure sulphur dioxide gas is evolved, which after passing a cooling arrangement can be used for the manufacture of sulphites or bisulphites.

—S. H.

VIII.—GLASS, POTTERY, AND EARTHENWARE.

An Improved Method of Preparing Glass for forming Coloured Designs thereon, and in the Means of Producing such Coloured Designs thereon. G. K. Cooke, London. Eng. Pat. 1431, February 2, 1885. 6d.

THE inventor flashes by fusion on one or both sides of flat glass one or more thin films of coloured glass. A "resist" of asphaltum-wax, or other material, is employed to form the design, either by itself or by leaving exposed in design on the glass. Suitable corrosive agents are used on either side, and on both sides when producing contrasts or combinations of colours.—T.

Process for Producing on Metal Plates a Layer of Material as a Substitute for Lithographic Stones. H. J. Haddan, London. From Julius Wezel, Saxony. Eng. Pat. 3305, March 13, 1885. 4d.

LITHOGRAPHIC stone, chalk, marble, lime, etc., are dissolved by means of sulphuric and hydrochloric acids, and from this solution "chalk combined with resinous or fatty acid" is precipitated by means of resin, or good soft soap. After the superfluous acid has been removed by filtration, the residuum is dried to a powder, which forms a mixture of lime in combination with fatty or resinous acid and sulphate of lime. The dry powder is distributed mechanically in a weak solution of soda, and blown on to the hot metal plate by a steam injector, or other suitable contrivance.—E. G. C.

Improvements in the Manufacture of Glass Articles Decorated with Stripes. W. Boulton, Andnan, Kingswinford. Eng. Pat. 8585, July 15, 1885. 6d.

THE inventor purposes to apply two or more stripes by a single act to the article to be decorated, or divide a single mass of decorating metal into two or more smaller masses, each of which may be used for the production of a decorated article. He details the manipulation by which the result is effected.—T.

Improvements in and relating to Glass Furnaces. From T. W. Synnott, of Wenoah, New Jersey, U.S.A. Eng. Pat. 13,685, November 10, 1885. 8d.

THIS invention is applied to the combination with a glass furnace of a tank for holding batch, or glass-making material, so that the operation of the furnace may be carried on continuously. There are numerous drawings illustrative of the construction and distribution of air and steam-flues—the glass holding tank-belt, the batch holding tank, and other parts. There are seventeen claims in the patent.—T.

IX.—BUILDING MATERIALS, CLAYS, MORTARS, AND CEMENTS.

New and Improved Building Material. E. Robbins, London. Eng. Pat. 12,803, September 25, 1884. 6d.

THIS invention consists of special methods to be employed in preparing, forming and finishing concrete materials for building and other purposes. Unground plaster is submitted to various processes, such as boiling, firing, pressure, induration by immersion in various liquids, treatment with tar, pitch, alkaline silicates, acids, dyes, sulphur vapour, etc.—E. G. C.

Non-conducting Compositions or Coatings. E. C. C. Stanford, Dumbarton. Eng. Pat. 13,312, October 8, 1884. 4d.

IMPROVEMENT on Eng. Pat. 2132, 1882. Inventor uses silicate of potash, soda or ammonia, in conjunction with wood-, peat-, seaweed-, or other form of charcoal, to which mixture he prefers to add a little lime, magnesia, alumina, or silica, in powder. With such addition the composition sets like cement.—E. G. C.

Improvements in the Manufacture of Portland Cement. H. J. Cooper, Wexford. Eng. Pat. 14,010, October 22, 1884. 4d.

THE inventor effects economy in fuel by utilising the heat of iron slag as it issues from the furnace in a molten state, and he adds to the slag, while in this condition, chalk, limestone or lime, afterwards thoroughly mixing the materials by passing the mass through rollers, mortar mills, or other suitable apparatus. If necessary, the operation may be continued by heating the mass in a furnace, heated by coal, coke or gas. It is completed by cooling and granulation, followed by pulverisation.—E. G. C.

Machinery for the Production of Concrete and Mortar. A. E. Carey and E. Latham, Newhaven and Liverpool. Eng. Pat. 14,115, October 25, 1884. 6d.

THE inventors refer to a previous patent, No. 1812, 1881, and under their present invention they effect the production of concrete and mortar by a single and gradual mixing of the required materials, instead of employing double mixing, as set forth for concrete in the above-mentioned patent.—E. G. C.

Furnaces for Burning Cement and other Substances. P. M. Justice, London. Communicated by C. Dietzsch, Germany. Eng. Pat. 14,324, October 29, 1884. 6d.

THE improved furnaces contain a cooling space, a burning space, a pre-heating space, and a connecting passage

between the pre-heating and burning spaces. The oblong form is better than the circular. The lining is formed of bricks, made by highly burning "marlstone of the dolomite formation," so that it forms a silicate soluble in hydrochloric acid, by mixing this silicate with burnt dolomite, moistening the material with water, and pressing it into the required form. The bricks so produced harden by exposure to the air, and may then either be used for lining the furnace, or first burnt.—E. G. C.

Imitation Marble. A. Bruce Joy and J. J. Lewen, London. Eng. Pat. 14,430, October 31, 1884. 2d.

CASTS of statues, etc., are made of plaster of Paris, mixed with zinc white (15–20 parts of the former to one of the latter), finely flaked mica being sometimes added. When quite dry, the casts are immersed in refined linseed oil, for six or seven days; they are then removed and allowed to stand in a warm place for four or five days. A mixture of old refined linseed oil and flake white is now applied to the surface, which is thus caused to present the appearance of old marble.—E. G. C.

Improved Artificial Stone. J. Thompson and J. H. Bryant. Eng. Pat. 15,014, November 14, 1884. 4d.

THIS artificial stone is manufactured from Portland cement, granite chippings, iron slag and silicate of soda, together with the requisite quantity of water. The proportions of the ingredients preferred by the inventors are—

Portland cement	15 parts by measure.
Crushed granite	15 " "
Crushed iron slag	40 " "
Silicate of soda	10 " "
Water	20 " "

100

—E. G. C.

Improvements in the Utilisation of a Waste Product. J. T. Welch, Carnarvon. Eng. Pat. 15,275, November 20, 1884. 4d.

THE debris of slate quarries is ground up and submitted to hydraulic pressure, to make it into blocks. These blocks, if dipped in potters' slip and burnt, furnish excellent bricks and tiles.—E. G. C.

Process for rendering Cements Hydraulic. W. P. Thompson, London. From R. Rosse and F. Wolters, Brunswick. Eng. Pat. 8153, July 6, 1885. 2d.

COMPOUND cements are rendered hydraulic—while, at the same time, their homogeneity and strength are increased—by a supplementary grinding in ball-mills or similar machines, which, by compression, bring closer together the smallest particles, and give them a lamellar structure.—E. G. C.

Machinery for Finely Dividing and Tempering Clay. W. P. Thompson, Liverpool and London. From Clayton Potts and A. Potts, Indiana, U.S.A. Eng. Pat. 8554, July 15, 1885. 6d.

CLAY is automatically pressed against a revolving cylinder, which removes successive portions from the mass, and so effects its disintegration.—E. G. C.

Improvements in Plastic Compounds. H. W. Merritt, Mass., U.S.A. Eng. Pat. 8736, July 20, 1885. 6d.

"ASBESTINE," a natural mineral deposit, consisting of silica 61.23 per cent., magnesia 31.37 per cent., alumina 1.99 per cent., ferrous oxide 0.37 per cent., and water 5.02 per cent., is ground to powder and mixed with quartz-sand and caustic soda or potash dissolved in water. The result is a plastic mass, "which can be worked and applied like mortar, and which, when spread and exposed to the air, turns as hard as a stone, without tendency to crack or crumble." When the plaster is

intended to be applied to smooth surfaces, as masonry or glass, etc., a small proportion of silicate of soda may be advantageously introduced.—E. G. C.

Preserving Stone. A. W. L. Reddie, London. From T. Eggleston, New York. Eng. Pat. 9087, July 28, 1885. 2d.

THE surface of the stone is saturated, according to the requirement of the particular case, with "fat-oil," with petroleum products dissolved in fat-oil, or with a compound of fat-oil, petroleum products, and sulphur.

—E. G. C.

Improvements in Method of and Apparatus for Vulcanising Rubber. F. W. Seabury, Providence, U.S.A. Eng. Pat. 10,058, August 25, 1885. 6d.

ACCORDING to this invention, the rubber is subjected to the action of superheated steam within a receptacle heated externally by an auxiliary furnace. All possibility of condensation of steam upon the rubber is in this manner avoided, and the utmost uniformity in the product is attained.—E. G. C.

Improvements in the Manufacture of Cement or Mortar. W. Keller, Aix-la-Chapelle. Eng. Pat. 13,639, Nov. 10, 1885. 4d.

THE cement or mortar manufactured according to this invention is composed of gypsum, cement, or any other binding agent, intimately mixed with pieces or fibres of metal, such, for example, as wire, or other metallic bodies imparting a fibrous nature to the product. The hardness of the product and its power of resisting tensile strain are said to be greatly increased.—E. G. C.

X.—METALLURGY, Etc.

The Extraction of Zinc from Burnt Pyrites. T. Meyer. Chem. Zeit. 1885, 1904.

OWING to the large percentage of zinc which is found in the Siegen pyrites, the burnt ore cannot be used in the blast furnace, and thus forms a troublesome by-product of the vitriol works. It is therefore very important to remove the zinc from the burnt ore and to convert it into a valuable product, and the author reports on some experiments made by him with that view, which, although they gave a negative result, may be of interest to others. The pyrites contained 40.47 per cent. sulphur and 8.92 per cent. zinc, whereas the burnt ore tested 8.05 per cent. sulphur and 12.54 per cent. zinc. After powdering and igniting it once more, it only contained 1.95 per cent. sulphur, which residue is probably present in the form of sulphates. The zinc must now be in the state of oxide. It was tried to extract the zinc oxide with a solution of ammonium sesquicarbonate, but although the digestion was kept up for eight hours, agitating all the while, only 30.6 per cent. of the zinc and 29.2 per cent. of the sulphur present in the burnt ore could be dissolved. This reaction can therefore not be made use of on the large scale, but it is worth mentioning that an analogous method for the extraction of zinc oxide, which is formed by the oxidation of zinc by steam, works very satisfactorily in the desilvering process of lead by means of zinc.—S. H.

The Application of Thomas-Slag as Artificial Manure. Chem. Zeit. 1886, 52, 83, and 103.

THE opponents of the application of Thomas-slag as an artificial manure, hold that by far the greater part of the phosphoric acid in the slag is combined with iron, and therefore not worth as much as calcium phosphate. L. Blum argues that this view contradicts the theory of the Thomas-process. At the commencement of the operation silicon and manganese combine with a small portion of iron, and afterwards the combustion of carbon and phosphorus takes place. Owing to the high temperature, the lime now acts on the metal slags formed,

liberating the oxides of the metals and combining with phosphoric and silicic acids. Lime, as the stronger base, deprives the salts of a less strong base of their acid, and the phosphates and silicates of iron and manganese are converted into the corresponding lime salts. This is also borne out in practice by the fact that if lime be deficient during the process, the dephosphorisation is incomplete. The slag running off at the end of the operation therefore contains the phosphoric acid chiefly as calcium phosphate. Maltzan, without taking any notice of Blum's paper, maintains that the phosphoric acid in Thomas-slag is combined with iron, and he dwells on the difficulty of dissolving iron phosphate, especially if this has been previously ignited. He characterises the slag as a phosphate of the least possible solubility. Furthermore, certain impurities of the slag, such as metallic iron (four per cent.), ferrous oxide (eighteen per cent.), calcium and iron sulphide (three per cent.), are injurious to the life of young plants. Another disadvantage is the presence of a high percentage of caustic lime (as much as twenty-five per cent.), which makes the application of ammonia salts quite impossible. Wherever the use of Thomas-slag proved successful, the application of lime would have had the same result, and slag costs eight times as much as lime. A great many patents have been taken out for the elimination of iron and caustic lime from the slag. The only rational method of working is to prepare dibasic calcium phosphate, as in Scheibler's patents, but this can only be done at an expense for hydrochloric acid, which makes the process unremunerative. Lately, however, the hydrochloric acid has been replaced by sulphur dioxide, which, mixed with air (waste gases from zinc or copper works, etc.), readily attacks the powdered slag, converting the caustic lime into gypsum and oxidising the metallic iron, as well as ferrous and manganous oxides and sulphides. By this treatment the consumption of hydrochloric acid is reduced to a third (owing to the insolubility of gypsum), and since all the iron compounds are converted into iron oxides, which are only slightly soluble in dilute hydrochloric acid, the extraction with this acid produces a solution of phosphoric acid, nearly free from iron. This solution may then be employed for the manufacture of precipitated phosphates.—S. H.

Improvements in the Manufacture of Iron and Steel. George Rowell, M.D., South Kensington, S.W. Eng. Pat. 1866, February 10, 1885. 8d.

A PART of the reduced iron is to be forced upwards from the crucible of the furnace through tubes situated in the walls, and to be blown in as a spray at the tuyères with the blast, with the object of reducing any ore which has escaped reduction. The metal is cast in ingots under pressure by means of a special apparatus described in the specification.—W. G. M.

Improvements in Separating Metals from their Ores, Refining Metals, Making Alloys of Metals, and Analogous Operations. Leon Quentin and Arthur Brin, Paris. Eng. Pat. 2025, February 13, 1885. 8d.

THE ore or metals to be reduced, refined, or alloyed, are placed, in a finely-divided condition and mixed with powdered coal, in a crucible which should be as free as possible from silica. Into the middle of the mass an earthenware pipe is introduced. The whole is heated to a "cherry red" in a suitable furnace, and then to a far higher temperature. Oxygen is then blown through the central tube, causing rapid oxidation of the fuel. The melted metal is finally poured into moulds.—W. G. M.

Improvements in Vessels or Baths for Galvanising, Tinning or Coating Iron or other Metal. William Henri Luther, Glasgow. Eng. Pat. 2126, February 16, 1885. 8d.

THE improved vessels consist of long troughs of cylindrical or other section, but with a contracted mouth running longitudinally, and fitted with vertical bars

placed at intervals to act as guides to the plates being dipped. The troughs are made either in one piece or of welded plates (not riveted), and are set in a flue running the entire length of the vessel, and communicating at one end with the fire-grate, and at the other with the chimney stack.—W. G. M.

Improvements in the Manufacture of Refractory Materials and other Fire-resisting Articles suitable for Lining Furnaces and Converters, and for other Uses. W. J. A. Donald, Glasgow. Eng. Pat. 2775, March 2, 1885. 6d.

IRISH lauxite or alum clay is calcined and then ground with sufficient milk of lime to form a paste. The product may be used for lining and cementing furnaces, in the manufacture of refractory bricks, retorts, crucibles, etc. A small quantity of uncalcined clay may in some cases be mixed with the calcined lauxite.—E. G. C.

Improved Metallic Etching for Producing Designs in Relief and in Two Colours. Alfred Piper, Wolverhampton. Eng. Pat. 3419, March 17, 1885. 8d.

UPON a surface prepared by electrolytically depositing one metal upon the surface of another of different colour, the design to be produced is painted in an acid-resisting medium, such as asphaltum varnish. The plate so prepared is then immersed in an acid which will attack the deposited metal where unprotected by the varnish. On removing the varnish by means of a suitable solvent, the design appears in relief in the plating metal on a frosted ground composed of the base metal.

—W. G. M.

Improvements in the Extraction of Compounds of Phosphorus from Phosphide of Iron or "Ferro-Phosphor." W. P. Thompson, Liverpool. From Luigi Imperatori, Düsseldorf, Prussia. Eng. Pat. 3761, March 24, 1885. 6d.

SOME works in Germany produce a pig-iron, containing ten to fifteen per cent. of phosphorus, which is known in the market as "ferro-phosphor." This invention relates to the extraction of phosphorus from that material in the form of alkaline phosphates. The process is as follows:—The crushed material is mixed with calcined potassium or sodium sulphate in such proportions that the alkali can combine with the whole of the phosphorus to form a normal phosphate. The mixture is placed in an ordinary rotating black-ash furnace and heated with continuous agitation to a low red heat. The phosphorus is oxidised to phosphoric anhydride, and the alkaline sulphate reduced. Sulphide and oxide of iron are produced at the same time, thus—

As soon as the mixture is fused it is discharged, and after cooling lixiviated with water at 30° C. The solution is concentrated and allowed to crystallise, whereby tribasic sodium phosphate ($\text{Na}_3\text{PO}_4 + 12\text{H}_2\text{O}$) is obtained. The crystals of the tribasic salt exposed to an atmosphere of carbon dioxide are converted into bibasic sodium phosphate and sodium carbonate, thus—

The crystals can be separated by crystallisation. The bibasic sodium phosphate may also be treated with an equivalent of calcium sulphate, whereby bibasic phosphate of lime and sodium sulphate are obtained. Or, the bibasic sodium phosphate is mixed with an equivalent of ammonium sulphate, to produce ammonium sodium phosphate. From the residues (iron sulphide and oxide) the sulphur may be recovered or the residues may be mixed and roasted with common salt, whereby hydrochloric acid and sodium sulphate are obtainable. The process may be further simplified by running the molten iron phosphide into the revolving furnace, in which salt-cake has previously been placed, in this case the furnace needs no heating. The rotation mixes the ingredients, and after a few revolutions the reaction is complete. The mass is then discharged and treated as already described.—S. H.

XI.—FATS, OILS, AND SOAP MANUFACTURE.

Improvements in the Production of Compounds which may be usefully employed for the Destruction of Insects on Plants or Animals, as Lubricants, for Sheep-dipping, and generally as Soaps or Detergents for Washing, Cleansing, and Purifying Purposes. C. T. Kingzett. Eng. Pat. 2210, February 17, 1885. 6d.

CRUDE turpentine or rosin is dissolved in sanitas-oil, or rosin-spirit, or rosin-oil, and is then saponified by caustic alkali solution, sp. gr. 1.300. Camphor is added to ensure a permanently fluid product, which is medicated by the addition of disinfectants, such as thymol, etc.

—W. L. C.

Improvements in the Production of Compounds or Mixtures to be used for the Destruction of Insects; also for Washing Animals; and generally as Soaps or Detergents; and for Purifying Purposes. C. T. Kingzett. Eng. Pat. 3855, March 25, 1885. 4d.

PETROLEUM spirit or thymol, with or without sanitas oil, etc., is mixed with rosin, or rosin oil, which is then saponified with caustic soda.—W. L. C.

Improvements in the Production of Liquid Soaps and other Liquids, which may be usefully employed as Insecticides; also for Washing Animals, and for Preserving and general Purifying Purposes. C. T. Kingzett. Eng. Pat. 3894, March 26, 1885. 6d.

ROSTIN or crude turpentine is dissolved in alcohol, and saponified by potash. To this may be added an alcoholic solution of a fatty-acid soap, and various disinfectants, etc., as well as the products mentioned in the two patents described above.—W. L. C.

A New or Improved Method of Scouring or Removing the Oil from Animal and Vegetable Substances by means of Infusorial Earth and Heat. L. A. Groth. Eng. Pat. 3977, March 25, 1885. 4d.

THE substance to be cleansed is heated with infusorial earth to 15° above the melting-point of the oil, and the whole is then washed with hot water.—W. L. C.

Improvements in Treating or Utilising Soap-suds. J. H. Ashwell. Eng. Pat. 6667, June 2, 1885. 4d.

TO liquor strongly charged with soapy or fatty matter, caustic or carbonated alkali is added, and the whole is kept at 125° F. A scum which rises is removed and decomposed by mineral acids, while the clear liquid is decolourised by animal charcoal, and used over again.

—W. L. C.

Improvements in Sheep-wash. R. Morris and W. G. Little. Eng. Pat. 14,098, November 18, 1885. 4d.

THE addition of glycerine to finely-divided solids, such as flowers of sulphur or white arsenic, when suspended in water, prevents them from aggregating together into a hard mass.—W. L. C.

XII.—PAINTS, VARNISHES, AND RESINS.

Improved Anti-fouling and Preservative Composition for Coating Ships' Bottoms, etc. J. S. Gisborne, Walthamstow. Eng. Pat. 312, January 9, 1885. 4d.

THIS composition, which may be applied in the usual way by a brush or otherwise, consists of the following ingredients:—Mercury, 10lb.; litharge, 9lb.; blende, zinc-white, white- or red-lead, or other like material, 14lb.; chalk (preferably in a finely-divided state) 15lb.; boiled linseed oil sufficient to form a pigment of the required consistency.—E. G. C.

An Improved Paint or Pigment. W. R. Lake, London. From J. P. Perkins, Illinois, U.S.A. Eng. Pat. 8737, July 20, 1885. 4d.

SILICATE slag from iron furnaces is extremely finely comminuted, when it unites with oil or other vehicles to form a product "having in a high degree all the valuable properties of iron paint, and having better flowing and

enduring qualities than any other iron-paint compound hitherto produced." Portions of the slag are selected, consisting of silicate of iron in a practically pure state, or with but a small admixture of foreign substances.

—E. G. C.

An Improved Varnish or Size. W. Macrom, Glasgow. Eng. Pat. 9413, August 7, 1885. 2d.

THIS varnish is suitable for sizing wall and other papers, fabrics, etc., preparatory to decorating them with dry colours; for waterproofing paper, felt, and other fabrics; and as a substitute for, or for mixing with, varnishes at present in use, in the manufacture of letterpress and lithographic printing inks, and for mixing with oil paints to secure against "skinning" while in bulk. The names of the ingredients of the varnish or size, and their approximate proportions, are as follow:—Odourless seed oil, 72 parts by weight; resin, 32; paraffin wax, 16; beeswax, 4; copal varnish, 1.—E. G. C.

Improvements in the Manufacture of Dry Colours. W. Macrom, Glasgow. Eng. Pat. 9414, August 7, 1885. 2d.

THE inventor dissolves aniline or other colouring substances in water or in methylated spirit (or in a mixture of the two), incorporates the dissolved colours with ground tale, kneads and dries by heat or exposure to the air, and finally pulverises them.—E. G. C.

Improvements in Machinery for Making Tubing and Cord of India-rubber, and other Materials, in a Plastic State. A. W. L. Reddie, London. From V. Royle and J. Royle, jun., Paterson, New Jersey, U.S.A. Eng. Pat. 10,357, September 1, 1885. 6d.

COMBINED with the pressure cylinder, presser and die of a machine for making tubing or covering wire, is a core made separate from the presser, with a core-bridge adjustable transversely to the axis of the core and die. The core-bridge serves to "adjust the core concentric with the die." Various other improvements are detailed in the specification.—E. G. C.

Improved Process of Hardening Balsams, Resins and Resinous Compounds or Products, Fats, Oils, Tar, Pitch and Bituminous Products. A. M. Clark, London. From Wirth & Co., Frankfort-on-the-Main. Eng. Pat. (amended November 30, 1885) 8036, May 21, 1884. 6d.

NATURAL pine resins and balsams, and the products obtained from the same, also fossil resins of the recent period, are found to attain a higher softening point when the acids contained in them are made to combine with caustic lime and other caustic alkaline earths, either partially or wholly. Fats, oils, pitch, and different kinds of tar can also be brought to a higher softening point, if mixed with resins, which have been hardened as above described. Alkalis must not be used in this process; in fact, by rendering the mass greasy, and forming with the resin a soap soluble in water, they do more harm than good.—E. G. C.

XIV.—AGRICULTURE, MANURES, Etc.

Direct Fixation of Atmospheric Nitrogen by Certain Argillaceous Soils. M. Berthelot. Compt. Rend. 101, 775—784.

THE source of the nitrogen compounds present in soils has long been discussed, but the question is still undecided. It appears certain that the loss of nitrogen by the decay of plants and the removal of crops, is not entirely compensated by the gain due to the nitric acid and ammonium nitrite formed in the atmosphere by the passage of electricity. The experiments described by the author show that certain soils have the power of absorbing free nitrogen from the air. Five distinct series of experiments were carried out simultaneously during two years, four different argillaceous soils being made use of.

Each kind of soil was simultaneously subjected to the following conditions during the two years:—(1) A portion of each was allowed to remain in a well-lighted room, the walls of which were newly cemented; (2) a portion was placed in a meadow under shelter; (3) a portion was placed on the top of a tower, 28 metres high, without shelter; (4) a portion was placed in vessels hermetically sealed; (5) a portion was subjected to sterilisation by heating.

Analyses of combined nitrogen (by the soda-lime process) of ammonia, of nitrates, and also of moisture, were made from time to time, and the results are given in the tables in the original paper.

(1.) The soils were placed in open glazed earthenware pots, each pot containing 50 to 60 kilos., and were kept in a dry, well-lighted room, freshly cemented on all sides. It was found that there was a continuous increase of combined nitrogen during the summer months, but not in winter, but that it bore no relation to the amount of ammonia or of nitrates, which sometimes increased slightly and sometimes decreased.

(2.) Glazed porcelain pots perforated at the bottom, and containing 1 kilo. of soil, were placed in a meadow, on trestles, under a small roof, to protect them from vertical rain. During dry weather they were watered with distilled water, the nitrogen in which had been determined.

(3.) Similar pots were placed on boards on the top of a tower, and were exposed to rain. During the whole period rain was collected in vessels of known surface, standing near the pots, and the nitrogen was determined. Atmospheric ammonia was also estimated by absorbing it in sheltered vessels, containing dilute sulphuric acid. The nitrogen absorbed by the soils was from four to eight times as great as the total nitrogen in the rain and in the atmosphere.

(4.) The soils were placed in white glass flasks, of four litres capacity, filled with air, and containing 1 kilo. of soil. The flasks were closed with ground stoppers, and some were kept in the dark, some exposed to light. A little water was added at first.

In all these cases there was a gradual increase of combined nitrogen, and since its amount bears no relation to that of ammoniacal nitrogen, or of the nitrogen of nitrates, it is clear that the element cannot be absorbed in the form of ammonia, or of nitrates, but as amido-compounds insoluble in water, such as are present in living organisms. The action, therefore, appeared to be due to micro-organisms; and this conclusion was borne out by the fact that after heating, the soils lost their power of absorbing nitrogen.

(5.) A kilo. of soil was placed in a flask of 4 litres capacity, and heated to a 100° for two hours, and finally exposed to the action of a current of steam for five minutes. The air which entered on cooling was filtered through cotton wool, soaked with hot glycerol. Even when exposed to the free air, and after a small quantity of unsterilised soil had been added, no increase of nitrogen was observed.

The subjoined table shows the general results of the research.

Substance.	Initial Nitrogen.	Closed Flask in light.	Closed Room.	Meadow.	Tower.
Yellow Argillaceous Sand	0.0910	0.1289	0.1179	0.0983	—
Yellow Argillaceous Sand	0.1119	0.1503	0.1639	0.1295	0.1396
Crude Kaolin	0.0210	0.0494	0.0407	0.0353	0.0557
Kaolin	0.1065	0.1236	—	0.1144	0.1497

The quantities of nitrogen are in grms. per kilo., and the increase was for the season, April to October, 1885.

According to Lawes and Gilbert, the gain of nitrogen due to salts dissolved in rain amounts to Skilos. per hectare, while at Montsouris the quantity was estimated at 1.7 kilos. per hectare. The quantity lost by the soil by the removal of crops, amounts to 50 to 60 kilos., so

that there must be a total loss of at least 40–50 kilos. per hectare. M. Berthelot calculates that, at the lowest estimate, the gain by absorption of free nitrogen is from 20 to 32 kilos., an amount which would be nearly, if not quite sufficient to balance the annual loss.

Papers have since been published by M. Joulie (*Compt. Rend.* 101, 1008–1011, and by M. Deherain, *Compt. Rend.* 101, 1273–1276), embodying results which are confirmatory of M. Berthelot's, in so far that under certain circumstances the soils examined contained more nitrogen at the end than at the beginning of the season. M. Joulie found a very much greater increase with argillaceous soil than with sand, but in both cases there was in general an increase of nitrogen. Both these chemists grew crops on the soils experimented on. M. Deherain draws attention to the suggestion of Lawes, Gilbert and Warrington, that soils may possibly obtain nitrates from subterranean water, but this could not have occurred in either M. Berthelot's or M. Joulie's experiments.—S. Y.

Utilising Basic Cinder as Manure. J. M. H. Munro, Downton; and T. Wrightson, Stockton-on-Tees. Eng. Pat. 250, January 7, 1885. 6d.

THE basic cinder is ground and mixed with ordinary or high grade superphosphate, in quantities insufficient to completely precipitate the soluble phosphate of the latter. In this way a manure is obtained containing soluble, precipitated, and undissolved (cinder) phosphates, all of high fertilising value. The unoxidised sulphur of the basic cinder is expelled as sulphuretted hydrogen gas. The proportion of oxides of iron in the product is not excessive. The drying properties of the alkaline cinder may be taken advantage of by mixing the cinder with superphosphates containing excess of acid or moisture. The high manurial value of the phosphates contained in ground basic cinder has recently been demonstrated by several series of experiments.—J. M. H. M.

Converting Scrap and Old Leather into Manure. James Ross, Old Kent Road, Surrey. Eng. Pat. 1835, February 10, 1885. 8d.

THE leather scrap is introduced into a vessel with a false bottom, perforated with holes. Below this are two steam jets opposite to each other, and above the vessel is covered by a sliding hood, the apex of which is connected with a series of U-tubes for condensing the waste steam and the ammonia evolved during the process. Sometimes horse-hoof parings are added to the old leather. The grease from the leather is liquefied, and collects in the space below the perforated plate. When the leather has been rendered sufficiently friable, it is ground to a powder, and sold as "torrefine."—J. M. H. M.

Preparing Phosphoric Acid for Use as Manure. François Barbe, 15, Rue Richelieu, Paris. Eng. Pat. 2193, February 17, 1885. 4d.

A SOLUTION of phosphoric acid, prepared by the action of sulphuric acid on bone phosphate, is evaporated to a syrup, which is absorbed by the addition of some porous material, such as finely-divided silica, infusorial earth, or sawdust.—J. M. H. M.

XV.—SUGAR, GUMS, STARCHES, Etc.

Source of the Presence of Raffinose (Mellitose) in the Products of the Manufacture of Sugar. E. von Lippmann. Ber. 18, 3087–3090.

IN furtherance of Tollens' investigations on the presence of raffinose in molasses, treated by the strontium process (this Journal, 4, 290), the author has successfully isolated this substance (which possesses such high rotating power on polarised light) from beet-juice, by subjecting the latter to the strontium process, as applied to the extraction of sugar from molasses. Hence the formerly supposed presence of raffinose in beet-juice is now an established fact.—D. B.

Improvements in the Process of Extracting Saccharine Matter. H. J. Haddan. From Conrad Frobach, Berlin. Eng. Pat. 1453, February 2, 1885. 6d.

THE molasses or other impure sugar solution is made into a solid mass by mixture with, and absorption by sawdust, or other finely-divided vegetable matter, and the mass is then lixiviated by strong alcohol. It is also preferred to treat the impure syrup previously to the above operations, by a modification of Marguerite's process, to remove sulphates.—A. J. K.

Improvements in Apparatus for the Decolorisation of Saccharine or other Liquor. Eng. Pat. 12,875, October 27, 1885. 8d.

Improvements in and relating to Bone-black Filters. Eng. Pat. 12,871, October 27, 1885. 8d.

An Improved Process and Apparatus for the Purification and Decolorisation of Sugar. Eng. Pat. 12,874, October 27, 1885. 8d.

All the above three Patents by W. R. Lake. From F. O. Mathiesen, New York.

THESE specifications relate to a process of continuous filtration of saccharine solutions upwards through a column of bone-black, to methods for supplying the liquor to the bone-black filters used, and to a description of the said bone-black filters, and of special apparatus for constantly removing the exhausted char and supplying its place by re-calcined bone-charcoal.—A. J. K.

XVI.—BREWING, WINES, SPIRITS, Etc.

An Improved Process of Brewing for obtaining Temperature or Non-intoxicating Beers. A. Manbré, London. Eng. Pat. 58, January 1, 1885. 6d.

THE inventor prepares beers from the ordinary brewing materials, which possess body and great nourishing properties, but only contain from 1 to 2 per cent. of alcohol. He makes his mash in a closed vessel, capable of resisting an internal pressure of 90 to 100 lb. per square inch, and in this he heats the malt (which is ground very finely, and the husk sifted out), or malt substitute with water to 175° F., until he finds that sufficient sugar has been formed to yield 1 to 2 per cent. of alcohol on fermentation. He then raises the temperature of the mash to 250–300° F. The worts so obtained are filtered, and then heated with the hops, or extract of hops, to the same temperature. After separation of the hops they are subjected to fermentation in the usual way. He claims that by heating the wort and wort and hops, to the above temperature, he renders the resulting beers more stable.—G. H. M.

Improvements in Preparing Gelatinised Grain for use in Brewing. J. Death, Cheshunt. Eng. Pat. 1032, January 24, 1885. 8d.

THE grain is gelatinised by means of a hot moist blast, which is obtained by injecting superheated steam into the flue of a smokeless fire. The blast is passed through cylinders, which contain the previously soaked grain. When the gelatinisation has reached a certain point the grain is withdrawn from the cylinders, and either dried on a malt-kiln and ground, or used direct in the mash-tun. Any kind or condition of grain may be used, and the time of steeping varies with the condition of the grain. The cylinders are made to revolve during the passage of the hot moist blast. A drawing of the furnace used, and a full description of the cylinders and other apparatus, accompany the specification.—G. H. M.

An Improved Method of, and Apparatus for Causing the Germination of Barley and other Cereals. W. R. Lake. From Gebr. Stollwerek, Cologne, Germany. Eng. Pat. 12,312, October 15, 1885. 8d.

THIS consists of an arrangement by means of which the temperature and aeration of barley, whilst undergoing germination, are placed under control. The barley or

other cereal, after being steeped in the usual manner, is placed in cylinders or drums, and the air passing through these is heated or cooled, as required, by previously circulating round pipes, filled with hot or cold water. The gases evolved during germination are removed either by an exhaustor or blower, which is connected with the heating and cooling arrangement. The apparatus employed is to some extent similar to that described in patents 1364 and 16,313, 1884, and aims at replacing the labour and uncertainty of working the grain upon the floors, as at present practised. Full descriptions and drawings of plant are given.—G. H. M.

XVII.—CHEMISTRY OF FOODS, SANITARY CHEMISTRY, DISINFECTANTS, Etc.

(A) CHEMISTRY OF FOODS.

Improvements relating to the Preparation of Ferments. Moritz Blumenthal, Grünan, Berlin. Eng. Pat. 5483, May 5, 1885. 8d.

THE invention relates to the separation of pure ferments from the organisms or substances containing the same. It contains severe criticisms on the existing methods of obtaining pepsin and rennet. Practically, he claims the use of saline solutions, with or without acids—using no “preservative” agent as such—such as boric acid, borax, glycerine, etc. He avails himself of the solubility of pepsin in acids, and of the insolubility of chymosin therein, to produce these substances respectively in a state of comparative purity. There are seven claims in the patent.—T.

Improvements in the Preservation of Fruit. J. E. Taylor, Ipswich. From W. Peacock, South Melbourne. Eng. Pat. 14,233, November 20, 1885. 4d.

THE fruit is placed in an air-tight box, the air from which is displaced by sulphurous anhydride by admission from the bottom. The odour of the gas is expelled when the fruit is subsequently boiled.—C. C. H.

(B) SANITARY CHEMISTRY.

A New or Improved Process for the Manufacture of a Filtering, Deodorising, and Decolourising Substance from Carbonaceous or “Lignite” Clay. G. H. Ellis, Exeter. Eng. Pat. 908, January 22, 1885. 4d.

CERTAIN carbonaceous or “lignite” clays are first pulverised and then introduced into tanks containing dilute soda or borax. The tanks are heated to 100° C., the mixture being thoroughly stirred until it becomes thick or pulpy. The material is then removed and spread upon drying floors, and after drying is broken up into rough lumps and carbonised in suitable retorts or ovens. During this operation, any sulphur present is removed by passing steam freely through the material. The desulphurised material is finally quenched in water, dried and granulated.—E. G. C.

Improvements in the Filtration and Purification of Liquids. J. G. Lorrain, London. Eng. Pat. 2352, February 21, 1885. 8d.

SPONGY platinum or platinum-black is deposited on extended porous surfaces, or on woven fabrics, and so exposed in a filter that a portion of the filtering surface is exposed to the action of the air. It is proposed to free water containing sewer gases from these gases by filtering the water through such a medium. The patentee shows seven different methods of forming his “platinised carbon” filters.—C. C. H.

Filtering Water or other Liquids. A. J. Bell, Manchester. Eng. Pat. 2746, March 2, 1885. 8d.

THE inventor places filtering material between two perforated plates, and, with a filter so constructed, closes the area of a water cistern near its upper edge, so that

all the incoming water must be partly filtered before it reaches the lower part of the cistern. He next secures in that lower part a series of similarly constructed upright filters, arranged in pairs with hollow spaces between, where the water collects after the second filtration, and is then withdrawn in a purified state.—B.

Improvements in the Method or Process of Treating Liquids or Solutions, etc., with Atmospheric Air and other Gases, in order to produce Oxidation, etc. W. F. B. Massey-Mainwaring and J. Edmunds, London. Eng. Pat. 2884, March 4, 1885. 8d.

A PORTION of the liquid is first highly oxygenated by forcing through it, in a closed vessel, compressed air; and a further portion of it is similarly purified by the introduction into its mass of the first part treated as above described.—C. C. H.

Improvements in the Treatment and Purification of Sewage. W. F. B. Massey-Mainwaring and J. Edmunds, London. Eng. Pat. 2885, March 4, 1885. 8d.

THE sewage may be first defecated by any of the methods well known, after which the effluent from the settling tank is oxidised by the injection of water, or any other liquid, which has been previously highly charged with oxygen under pressure. Rapid oxidation of the organic matter contained in it, is stated to be the result.—C. C. H.

Improvements in Disinfectant and Cleansing Liquid. H. Endemann, Brooklyn. Eng. Pat. 14,391, November 24, 1885. 4d.

THREE HUNDRED gallons of coal-tar oil 1.04 specific gravity, and 100 gallons of spirits of wood tar 0.930 specific gravity are mixed. To 100 gallons of this mixture are added 200lb. of oleic soap, prepared with caustic potash, and containing 43 per cent. of oleic acid. To the whole bulk of the mixture are then added 435lb. of potash solution, prepared by dissolving 6 parts of caustic potash with 46 parts of water.—C. C. H.

Purification and Filtration of Waters, Sewage, and other Liquids. P. Smith and R. Wild, Manchester and Littleborough. Eng. Pat. 16,514, December 16, 1884. 6d.

ONE gallon of a solution of “aluminous cake,” or sulphate of alumina, is added to every 50 gallons of water or sewage, and the effluent is passed through an improved filter, the upper part of which is provided with an open or covered receiving tank. From this tank or chamber, the fluid passes downwards through a perforated grating, and through the filtering materials found most suitable (by preference charcoal or carbon), then through another grating, covered with cotton, linen, or asbestos cloth, into a chamber beneath, from which the filtered water rises into a suitable pipe, passage, or chamber, which is the outlet. After rising to a suitable height, as may be most convenient, the fluid is allowed to overflow and pass into a stream.—E. G. C.

(C) DISINFECTANTS.

Improvements in Disinfectants. J. C. Stevenson, M.P., Westoe. Eng. Pat. 2739, February 28, 1885. 4d.

BISULPHATE of soda, containing about 40 per cent. of sulphuric acid, is mixed with manganate of soda, and the whole finely ground. When brought into solution, the acid salt of soda acts in precisely the same manner in the production of the permanganate salt as if free sulphuric acid had been employed.—C. C. H.

XVIII.—ELECTRO-CHEMISTRY.

Improvements in Galvanic or Primary Batteries. C. M. Newton, Tulse Hill, London. Eng. Pat. 1088, January 26, 1885.

IN galvanic or primary batteries, the author uses oxide of lead as a depolarising body, together with a single liquid or solution of caustic potash or caustic soda, or a mixture of both these caustic alkalis, as an exciting liquid.—W. B.

Improvements in Secondary Batteries. J. S. Sellon, London. Eng. Pat. 1764, February 9, 1885.

AN invention in secondary batteries to obviate the occurrence of contacts between the negative and positive elements by the coming together of the plates at any point or points, or the falling off or out therefrom of packed material, and to obtain arrangements by which the plate or all the plates of either pole in a cell may be, with facility, removed and examined, and be readily replaced for any required purpose; and also, that an effective and economical battery can be so constructed that it may occupy a minimum of space. The elements or plates of one pole are placed transversely through openings in the elements or plates of the other pole.

—W. B.

The Construction of Storage or Secondary Batteries or Electric Accumulators. W. Symons, Barnstaple. Eng. Pat. 2747, March 2, 1885.

BATTERIES are constructed chiefly or entirely of carbon in plates, rods, or cylinders, in which cavities or spaces are made for containing oxide of lead or other suitable material. The carbon plates are connected together in proper series, either by simple pressure or gravity, or by plates or wires of silver or other conducting material not acted upon by the liquid.—W. B.

Improvements in Secondary Batteries. H. J. Allison, London. From P. Benjamin, New York. Eng. Pat. 2795, March 3, 1885.

THIS invention consists of a new secondary or storage cell in which a liquid is used consisting of a solution of zinc sulphate, to which magnesium oxide is added, and electrodes specially compounded or prepared.—W. B.

Improvements in Secondary Batteries or Accumulators. J. Pitkin, Clerkenwell, Middlesex. Eng. Pat. 3260, March 12, 1885.

THIS patent relates to the construction of the elements of a voltaic battery, the combination with a conductive plate or other form of conductor, of one or two perforated plates of non-conducting material, enclosing one or both faces of the conducting plate and intermediate distance pieces, frames, ribs or flanges, the whole united by bolts of non-conducting material, for the purpose of holding the active material in contact with the conducting plate.

—W. B.

Improvements in Electric Batteries. W. R. Lake, London. From H. L. Brevort and I. L. Roberts, Brooklyn, New York. Eng. Pat. 3798, March 24, 1885.

A BATTERY carbon and a reservoir or liquid-holder are arranged in an electric battery at the upper portion of the said carbon, and communicating with the pores or interstices of the carbon, so that liquid will be supplied from it to the carbon, and will percolate thence towards the liquid in the cell of the battery.—W. B.

An Improved Galvanic Battery. H. J. Allison, London. From E. M. Gardner, Massachusetts, U.S.A. Eng. Pat. 12,170, October 13, 1885.

THE principal of this invention is to provide a partition in a galvanic cell which shall offer the least resistance to

the current, and at the same time ample path for the transference of matter, and which shall be of a material not itself chemically alterable by or capable of chemically altering the fluids in which it is immersed. Carbon being an electrical conductor, and affording a path through its substance for the current, while the hydrogen passes through its pores, is found to be most suitable.—W. B.

XIX.—PAPER, PASTEBOARD, Etc.

An Improved Process of Preparing a Lye for and Method of Extracting Cellulose from Wood. From August Fellner, A. Albutt, Eng. Pat. 16,186, 6d.

THIS process consists in heating wood to a temperature of 150° C., with a solution obtained by acting upon magnesite and dolomite, either together or singly, with sulphurous acid.—E. J. B.

XX.—FINE CHEMICALS, ALKALOIDS, ESSENCES, AND EXTRACTS.

Piperidine from Pentamethylenediamine. A. Ladenburg. Ber. 18, 3100—3102.

THE author has effected the decomposition of pentamethylenediamine into piperidine and ammonia by subjecting pentamethylenediamine hydrochloride to distillation.—D. B.

XXII.—GENERAL ANALYTICAL CHEMISTRY.

Drying and Heating Apparatus for Chemical Laboratories. V. Meyer. Ber. 18, 2999—3002.

THIS apparatus consists of a small jacketed cylindrical copper bath with elliptic base resting on three legs. To maintain a uniform temperature in the bath the jacket is charged with a small quantity of a liquid having a constant boiling point. The bath is then heated gently in order to vaporise the liquid. To prevent loss by evaporation a small condensing tube is fitted into the top of the jacket. As heating agents the following substances are used:—Water gives a temperature of 97° in the interior of the bath, toluene gives 107°, xylene 136°, anisole 150°, and coal-tar cumene 161—162°. For temperatures above 200° naphthalene may be employed. The apparatus may be procured from C. Desaga of Heidelberg.—D. B.

Estimation of Phosphorus in Iron and Steel. J. B. Mackintosh. Trans. Amer. Inst. Mining Eng. 1885.

THE general method has been to dissolve the sample in some oxidising agent, in order to convert the phosphorus into phosphoric acid. M. Y. Lantin (*Chem. News*, xviii, p. 252), however, proposed to liberate the phosphorus as hydrogen compound, by attacking the metal with hydrochloric acid. The evolved gases were passed first through potash solution, and then through silver nitrate solution, by which the phosphorus carried over was obtained as silver phosphide, which was treated with nitro-hydrochloric acid, and the phosphoric acid resulting determined as magnesium pyrophosphate. The author found that the whole of the phosphorus was not obtained by Lantin's method; only a portion of it going over as gas, the remainder occurring partly in the insoluble residue, and partly in solution in the dissolving flask. On taking the solution from the dissolving flask and attempting to precipitate the phosphorus with a little iron as basic phosphate by means of an alkaline acetate, it was found that only a portion of the phosphorus in solution could be thus precipitated. Thus, a pig-iron containing 0.880—0.885 per cent. of phosphorus was found to give only 0.771 when the solution was treated with alkaline acetate without previous oxidation, although the phosphorus left in the residue and that carried off in the gaseous state were included. In this experiment the gases evolved were not passed through potash and silver nitrate solutions, these being replaced

by an acidulated solution of potassium permanganate. A current of oxygen was passed through the apparatus during the time the iron was dissolving, but the low result obtained shows that oxygen alone was not sufficient to convert the whole of the phosphorus dissolved into a form precipitable by alkaline acetate. That the loss of phosphorus is due to defective oxidation, the author shows by taking half the solution obtained in several experiments and oxidising by means of nitric acid and potassium chlorate, and afterwards precipitating with acetate; in this way the whole of the phosphorus could be accounted for, so that the problem resolved itself into finding a method of converting the lower oxygen compounds of phosphorus into phosphoric acid, without simultaneously oxidising ferrous to ferric iron. This led to a satisfactory method, of which the following is a brief outline:—

"1. Solution in hydrochloric acid in a stream of oxygen or air, absorbing the escaping gases in potassium permanganate acidified with sulphuric acid. 2. Heating the solution to boiling, stopping the passage of the oxygen current, and carefully adding an excess of sulphurous acid solution, and continuing the boiling till the precipitated MnO_2 in the absorption flasks is redissolved. This boiling should last several minutes to ensure the completion of the reaction." 3. Disconnecting and allowing to cool. "4. Mixing solutions, filtering out residue, which is placed (with filter paper) in a porcelain capsule, oxidising with nitric acid and potassium chlorate, and evaporating to dryness. 5. Boiling the solution till the excess of sulphurous acid is expelled," and precipitating the phosphorus as iron phosphate along with a little basic iron acetate, by means of alkaline acetate. The filtrate is again boiled, by which a further precipitate of basic iron acetate is obtained which ensures the obtainment of all the phosphoric acid. 6. Dissolving these precipitates in hydrochloric acid and adding this to the solution of the residue in which, by this time, the paper will have been thoroughly destroyed. 7. Evaporating to dryness for silica, and proceeding as usual to precipitate the phosphorus as ammonia-phosphomolybdate by means of ammonium molybdate in a nitric acid solution in presence of ammonium nitrate. The less phosphorus is present the less time is required by this process in comparison with other methods of estimating phosphorus.—J. T.

New Books.

OUTLINES OF ORGANIC CHEMISTRY. By H. FORSTER MORLEY, M.A., D.Sc., Fellow of, and Assistant-Professor of Chemistry at University College, London. London: J. & A. Churchill, 11, New Burlington Street, 1886.

8vo volume containing preface, table of contents, and 471 pages of subject matter. Finally, follow a SUMMARY OF GENERAL REACTIONS, a LIST OF EXPERIMENTS to be performed by the student, subdivided into Tests and Preparations, and an ALPHABETICAL INDEX. The Table of Contents furnishes a key to the arrangement of the work, which is briefly indicated as follows: Analysis; Methyl Compounds; Ethylic Alcohol; Acetyl Compounds; Ethyl Compounds; Compounds containing Nitrogen; Compounds containing Phosphorus; Compounds containing Metals; Homology and Isomerism; Compounds containing two Hydroxyls and bodies related to them; Glycerine Group; Starch and Sugar Group; Cyanogen Group; Polybasic Acids; Unsaturated Compounds; Chlorinated Compounds; Amido Acids; Oxy-Acids; Uric Acid Group; Derivatives of Cyanamide; Sulphocyanides. DERIVATIVES OF BENZENE: Benzene; Homologues of Benzene; Nitrosamines; Nitroso Compounds; Azo Compounds; Hydrazines; Phenols; Benzyl Compounds; Carboxylic Acids; Compounds with two Benzene Nuclei; Rosaniline; Phthalein Group; Indigo; Azo-colouring Matters. DERIVA-

TIVES OF NAPHTHALENE. DERIVATIVES OF PHENANTHRENE. DERIVATIVES OF ANTHRACENE. DERIVATIVES OF THIOPHEN. ALKALOIDS. Tobacco; Hemlock; Opium; Nux Vomica; Cinchona; Sabadilla; Monkshood; Deadly Nightshade. DERIVATIVES OF PYRIDINE. TERPENES. UNDEFINED COMPOUNDS. BILE. PHYSICAL CONSTANTS.

LEHRBUCH DER KOHLENSTOFFVERBINDUNGEN, ODER DER ORGANISCHEN CHEMIE. VON CARL SCHÖRLEMMER. Dritte verbesserte Auflage. Mit eingedruckten Holzstichen. Erste Hälfte. Braunschweig. Druck und Verlag von Friedrich Vieweg und Sohn, 1885.

THE above is the first half of the entire work, and commences with an "Einleitung," which is treated as part of the text and is mainly devoted to a criticism of the older method of dividing the science into Inorganic and Organic Chemistry, finally disclosing the more correct title for the latter division, as the Chemistry of the Carbon Compounds. The text covers 471 pages of the small 8vo volume, and this the first half of the work concludes with the Sugars, Dextrin, Pyrrrol, etc., and lastly a "Nachtrag" treating of the "Nitroso- und Isonitrosoverbindungen."

DIE GESAMMTE INDIGO-KÜPENBLAU-FAERBEREI, RESERVAGE UND NETZ-DRUCKEREI (BLAUDRUCK) AUF BAUMWOLLE UND LEINEN. Enthaltend die in neuerer und neuester Zeit in Aufnahme gekommenen Herstellungsmethoden, Reservagen und Aetzungen, auch farbige, auf indigoblauen Grunde. Nach Mittheilungen und Notizen von Persoz, Mercer, Walter Crum, Thompson, Prudhomme, O. Scheurer, Saget, Witz, D. Köchlin, A. Schulz, Fries, Bourcart, Jos. Dépierre, J. Ribbert, Schlieper and Baum, Ernst, Chadwick, u. Anderen. Gesammelt und zusammengestellt, von E. RUDOLF, Leipzig. Verlag von Gustav Weigel, 1885.

SMALL 8vo volume in paper cover. Price, 6s. (6 Mark). It contains a brief preface, table of contents, and 104 pages of subject-matter devoted to a compilation of the best methods of dyeing and printing with indigo, according to the writings or recipes of the above-named authorities.

THE CHEMISTRY OF THE COAL-TAR COLOURS. Translated from the German of Dr. R. BENEDIKT, and edited, with additions, by E. KNECHT, Ph.D., Head Master of the Dyeing Department of the Technical College, Bradford; Editor of the *Journal of the Society of Dyers and Colourists*. London: George Bell & Sons, York Street, Covent Garden, 1886.

8vo volume bound in cloth, and forming one of the well-known series of Technological Hand-books. The work contains a preface, table of contents, and subject matter filling 243 pages. An alphabetical index concludes the work. A fairly correct idea of the matter contained in the text and of its sub-division, is conveyed in the following excerpt from the Table of Contents: The Optical Properties of Colouring Matters; Absorption Spectra of the most perfect Colouring Matters; General Chemical Properties of the Colouring Matters, Methods for Dissolving the Colouring Matters. Dyeing with Coal-tar Colours. The Relations of the Fibres to Colouring Matters; the Testing of Colouring Matters; Coal Tar; the Coal-tar Colours; I. Aniline Dyes; II. Phenol Dye-stuffs; III. The Azo Dyes; IV. Artificial Indigo; V. the Anthracene Colouring Matters.

Monthly Patent List.

I.—GENERAL PLANT, APPARATUS, AND MACHINERY.

APPLICATIONS.

1885.

- 1001 A. J. Boulton, London.—Communicated by G. A. Heiser, Germany. Improvements in smoke consuming furnaces and boilers. January 22
- 1037 J. L. Wade, Glasgow. An improved compound for preventing and removing incrustation in steam boilers. Jan. 23
- 1228 H. Thompson, London. Improvements in furnaces. January 27
- 1213 A. Fould and P. Genreau, London. Manufacture of refractory bricks, tiles, tubes, crucibles, furnace linings, and other articles subjected to high temperatures. January 27
- 1352 H. Scott, Newcastle-on-Tyne. Improvements in and connected with furnaces, whereby chimneys are dispensed with, and the heating properties of coal, coke, and other fuel increased, and the smoke entirely consumed. January 30
- 1391 H. Maus, London. Improved apparatus for feeding furnaces with fuel without at the same time admitting air. January 30
- 1420 J. Payne, Cardiff. The coating of steam pipes, hot-water pipes, hot-air pipes, cold-water pipes, and steam boilers, for the retention of heat and exclusion of cold. February 1
- 1436 H. Kosicke, London. Improvements in smoke-consuming furnaces. Complete specification. February 1
- 1490 W. Mills, T. Pickup, and G. Procter, London. Improvements in apparatus for the separation of smoke from the gases evolved during the combustion of fuel. February 2
- 1517 J. S. Badia, London. Improvements in automatic apparatus for generating gases. Complete specification. Feb. 2
- 1613 B. W. Maughan, London; and S. F. Sloper, Wandsworth. Improvements in apparatus for cooling and heating air or water or other liquids, and the production of heat and light. February 4
- 1794 W. B. G. Bennett, London. Improvements in apparatus for mixing or incorporating solid and liquid matters, and for effecting or controlling the supply of the matters to be mixed, and for effecting or controlling the discharge of the same when mixed. February 6
- 1990 J. Mactear, Glasgow.—Communicated by J. Kolb, France. Improvements in raising liquids, and in apparatus therefor. February 11
- 2056 W. F. Bower, Peckham. Cooling liquids of any description by compressed air. February 12
- 2091 C. G. P. de Laval, London. Improved centrifugal apparatus that can be operated by hand for separating substances of different gravities, such as milk and cream. February 12
- 2096 J. Maugnnli and W. Bratby, Manchester. An improved system of saturating liquids with or exposing them to the action of gases, and apparatus connected therewith. Feb. 13
- 2137 J. Marx, London. Machinery or apparatus for effecting the separation of liquid from solid matter. February 13
- 2168 G. Behrens, London. Improvements in filtering apparatus. Complete specification. February 15
- 2182 F. Grosvenor, Glasgow. Improvements in filters or water purifiers. Complete specification. February 15
- 2252 L. Douillet, Liverpool. Improvements in metallic casks or drums. Complete specification. February 16
- 2376 S. Fox, London. Improved means of preventing incrustation of certain parts of steam boilers. February 18
- 2401 G. M. Capell, London. An improved construction of apparatus for effecting industrial desiccation. February 18
- 2478 A. Higginson, Liverpool. Improvements in the construction of steam generators, furnace flues, and like structures. February 20
- 2503 J. Gray, Glasgow. Improvements in centrifugal machines for separating fluids of different specific gravity. February 20

COMPLETE SPECIFICATIONS ACCEPTED.*

1885.

- 3055 R. J. Friswell and A. Myall. Filter presses. Feb. 16
- 3740 J. Price, jun. Apparatus for heating or cooling liquids, condensing steam, and for like purposes. February 2
- 3924 L. W. Sutcliffe. Self-feeding and smoke-consuming furnaces and appliances for heating muffles and drying stoves, etc. January 26
- 4377 T. W. Barber. A tyure apparatus for supplying and heating blast. January 26
- 4710 M. Keenan. Non-conducting composition for protecting boilers, cylinders, pipes, etc., against radiation. Feb. 2
- 4711 M. Keenan. Means for protecting boilers, cylinders, pipes, etc., against radiation. February 2
- 4831 C. Jones. Improvements in apparatus used when heating vessels or chambers by steam-heated jackets. February 16
- 15865 W. R. Jones. Duplex furnaces specially adapted for burning breeze and inferior fuel. February 16

15873 F. Bruggemans and L. Donkers. Improvements in or applicable to internally heated boilers, for the purpose of economising fuel. January 26

1886.

599 N. Evans. Apparatus for supplying air to furnaces and combustion chambers, especially steam generators. February 16

II.—FUEL, GAS, AND LIGHT.

APPLICATIONS.

- 996 G. Waller, Westminster. Improvements in gas retort lids, mouth-pieces, and fastenings. Complete specification. January 22
- 1226 J. West, Westminster. Improvements in machinery or apparatus for charging and drawing gas retorts. January 27
- 1367 G. Kinnaird, Glasgow. An inodorous gas calorific, for use also with oil, spirit, or other substances. January 30
- 1459 J. L. Balfour and J. Lane, London. Improvements in the manufacture of illuminating gas and volatile liquid hydrocarbons. February 1
- 1461 J. J. R. Humes, London. Improved means for mixing and igniting combustible charges operating liquid hydrocarbon engines. February 1
- 1543 G. Ignatieff, London. Improvements in electric candles. February 2
- 1556 C. Pilla, London. Improvements in the manufacture of gas, and apparatus therefor. February 2
- 1695 D. Yates, Halifax. Improvements in the manufacture of fire-lighters. February 5
- 1711 R. W. Hewett, Birmingham. Improvements in the application of an exhaust or egressing current of air obtained from a fan, blower, bellows, or exhauster, for the better consumption of fuel and economy of heat in firebricks, stoves, furnaces, steam, and other boilers. February 5
- 1807 W. S. Morland, Hempstead, Gloucester. An improved method of removing and discharging the material used in gas purifiers. February 8
- 1960 A. G. Holbrook, Westminster. Improvements in machinery and apparatus for charging and drawing gas retorts. February 10
- 2045 P. Smith and R. Wild, Manchester. Improvements in the means and method for lighting and illuminative purposes. February 12
- 2270 A. Kitt, London. Improvements relating to the manufacture of coal-gas. February 16
- 2307 H. Barclay and R. Simpson, Harrington, Cumberland. Improvements in the manufacture of coke for metallurgical purposes. February 17
- 2411 A. Dempster, Elland, Yorks. Improvements in centre valves for working purifiers and other apparatus used in the manufacture of coal-gas. February 18
- 2412 A. Dempster, Elland. Improvements in apparatus, and in the means used in purifying coal-gas. February 18
- 2498 G. Beard, Glasgow. Improvements in heating feed water, and in utilising the waste heat of what are sometimes known as "low-heating furnaces" and other furnaces. February 20
- 2572 W. Kemble, London. Improvements in apparatus for regulating the production and delivery of gas from gas-making apparatus. February 22

COMPLETE SPECIFICATIONS ACCEPTED.

1885.

- 3790 W. Black. Manufacture of briquettes or fuel blocks. February 2
- 2570 R. Dempster, jun. Condensers used in the manufacture or purification of gas. February 12
- 4411 W. Black. Treating coal dross and other carbonaceous substances. February 2
- 4461 A. Klonne. Improvement in gas washers called column washers. February 16

1886.

- 451 J. Parkes. Apparatus for enriching illuminating gas. February 16
- 996 G. Waller. Gas retort lids, mouth-pieces, and fastenings. February 23

III.—DESTRUCTIVE DISTILLATION, TAR PRODUCTS, ETC.

APPLICATIONS.

- 1016 H. Kenyon, Manchester. Improvements in the distillation and decomposition of coal, shale and other matters, to obtain illuminating gas and other products. Complete specification. January 23
- 1017 H. Kenyon, Manchester. Improvements in ovens or retorts and connected apparatus for use in the distillation and decomposition of coal, shale, and other matters. Complete specification. January 23

COMPLETE SPECIFICATIONS ACCEPTED.

1885.

- 4902 A. Neilson and J. Snodgrass. Obtaining ammonia in connection with the distillation of oil-yielding or carbonaceous minerals. February 12

* The dates given are the dates of the Official Journals in which acceptances of the Complete Specifications are advertised. Specifications thus advertised are open to inspection at the Patent Office immediately, and to opposition within two months of the said dates.

5002 H. Simon and W. Charlton. Improvements in hydraulic mains and valves for conducting gases and other products of distillation from coke-ovens, gas-retorts, gas-producers, etc. February 23

5073 L. Mond. Separation of ammoniacal products and tar from producer or other furnace gases. February 16

12298 H. Stier. Process of extracting from carboniferous materials the products met with, the processes of converting into gases, and of withdrawing gases (for instance, process of distilling, of smouldering, and the like). January 26

IV.—COLOURING MATTERS AND DYES.

APPLICATIONS.

1636 A. M. Clark, London.—Communicated by the Farbfabrik vormals Branner, Germany, through Wirth & Co., Frankfurt. The manufacture of a new beta-naphtholmonosulpho acid, and products therefrom. February 4

2983 W. R. Lake, London.—Communicated by A. E. Spencer, United States. Improvements relating to blueing for laundry purposes, and to means for facilitating the use of the same. Complete specification. February 12

2213 C. A. Martius, Berlin. Improvements in the production of mixed azo-colours. February 15

COMPLETE SPECIFICATIONS ACCEPTED.

1885.

3889 J. Inray.—Communicated by J. Boasboason. Manufacture of blue and violet colouring matters by oxidation of the thio-bases of diamines. January 29

15775 H. H. Lake.—Communicated by The Schoellkopf Aniline and Chemical Co. Improvements in and relating to colouring matters. January 26

15781 H. H. Lake (The Schoellkopf Aniline and Chemical Co.) Improvements in and relating to colouring matters. January 26

V.—TEXTILES: COTTON, WOOL, SILK, Etc.

APPLICATIONS.

1896 W. R. Lake, London.—Communicated by H. R. Randall, United States. Improvements relating to the treatment of silk cocoons, raw silk, or the like. Complete specification. February 9

2226 J. P. Land and C. P. Ring, London. An improved apparatus for carbonising and destroying vegetable matter in wool. Complete specification. February 16

COMPLETE SPECIFICATIONS ACCEPTED.

1885.

5512 B. Hallett and T. F. Wiley. Method of applying waterproofing material to pile and other goods. February 16

15906 T. F. Wiley. Process of treating textile fabrics to render them waterproof. January 29

VI.—DYEING, CALICO PRINTING, PAPER STAINING, AND BLEACHING.

APPLICATIONS.

1121 W. Birch, Manchester. Improved apparatus to be employed in washing, soaping, dyeing, and dunging woven fabrics. Complete specification. February 1

1465 H. Horner, London.—Communicated by C. C. Sabin, Canada. Improvements in and apparatus for blueing water for laundry and other purposes. February 1

1182 J. Coulter, Halifax. Improvements in "hawking" machines for indigo-dyeing. February 2

1577 F. A. Gatty and V. H. Gatty, Manchester. Printing and discharging various colours upon cotton fabrics dyed with a certain dye. February 3

1621 J. Aimers, Galashields. Scouring wool or other fibrous substances. February 4

1627 P. B. Wilson, Glasgow. "Zweimal gedruckt" for printing designs of one or more colours on both sides of the cloth at one operation, and to give exact fitting on cotton, cloth, silk, wool, linen, and paper, or any other material. February 4

1750 W. G. White, London. Improvements in dyeing fabrics, and in apparatus used for that purpose. February 5

2051 R. H. Ainsworth and E. B. Manby, London. Improvements in apparatus for bleaching light and heavy textile fabrics and other materials by the "Thompson" and other analogous processes, which are also applicable for dyeing purposes. February 12

VII.—ACIDS, ALKALIS, AND SALTS.

APPLICATIONS.

1018 L. Mond, London. Improvements in obtaining ammonia and hydrochloric acid from ammonium chloride. January 23

1019 L. Mond, London. Improvements in obtaining ammonia and chlorine from ammonium chloride. Jan. 23

1050 W. Bramley, London. Improvements in the manufacture of carbonates or bicarbonates of sodium or potassium from their sulphates. January 23

1241 A. Fould and P. Genreau, London. Process for obtaining magnesia or mixtures of magnesia and lime suitable for the manufacture of refractory articles and other purposes. January 27

1288 G. Perry, London.—Communicated by M. Perry, New South Wales. Improvements in obtaining compounds of cobalt from solutions containing the same. January 28

1289 G. Perry, London.—Communicated by M. Perry, New South Wales. Improvements in obtaining compounds of cobalt from solutions containing the same. January 28

1831 A. McDonald Graham, London. An improved process for manufacturing sulphates of metals from their oxides. February 8

1832 A. M. Clark, London.—Communicated by O. Eyckens, France. An improved method of producing lead-salts generally, and especially carbonate or oxycarbonate of lead (white lead). February 8

1861 G. H. Nichols, W. H. Nichols, and J. B. F. Herreshoff, London. An improved sulphuric acid tower. Complete specification. February 9

1881 J. J. Hood and A. G. Salamon, London. Improvements in the preparation of aluminium compounds. February 9

1915 J. Mactear, Glasgow.—Communicated by J. Kolb, France. Improvements in obtaining chlorides of barium and strontium. February 10

1989 J. Mactear, Glasgow. Improvements in preparing soda for sale and distribution. February 11

2207 H. J. Leslie, London.—Communicated by R. Finch, Germany. Improvements in the concentration of sulphuric acid, and in apparatus for that purpose. February 15

2233 M. R. Pryor, Stevenage, and A. C. Jameson, London. Improvements in the extraction of nitrate of soda and other salts. Complete specification. February 16

2262 E. Luhmann and C. G. Rommenhöller, London. An improved measuring apparatus for liquid carbonic acid. Complete specification. February 16

2335 H. H. Wilson, London. Improvements in the process and apparatus for the manufacture of anhydrous sulphuric acid. February 17

COMPLETE SPECIFICATIONS ACCEPTED.

1885.

1982 W. L. Wise.—Communicated by R. Radot. Apparatus for decarbonating carbonate of barium and carbonate of strontium. January 29

3933 F. S. Newall. Treatment of alkali-waste to obtain useful products. January 29

1025 J. J. T. Schlesing. Manufacture of carbonate of soda by aid of ammonia. January 26

1274 H. Gaskell, jun. Treatment of bicarbonate of soda for obtaining useful products therefrom. February 19

1285 G. Attwood. Means for the continuous oxidising and desulphurising of ores or minerals. January 26

1902 A. Neilson and J. Snodgrass. Obtaining ammonia in connection with the distillation of oil-yielding or carbonaceous minerals. February 12

8973 L. Mond. Separating ammoniacal products and tar from producer or other furnace gases. February 16

12745 W. R. Lake.—Communicated by T. Schmidtborn and D. Jarves. Manufacture of ammonium chloride and potassium sulphate. February 9

1886.

719 A. Osenbrück. Manufacture of anhydrous ammonia, and utilisation thereof for production of cold or work or both. February 23

VIII.—GLASS, POTTERY, AND EARTHENWARE.

APPLICATIONS.

1089 A. Shaw, Longton, Staff. A novel application of earthenware, china, or fireclay in connection with water-closet cisterns. January 25

1129 H. H. Redfern, Hanley. Improvements in enamel, hardening-on, and other kilns. January 26

1411 J. Haley, Manchester. Glass files, and the process of making the same. February 1

1563 W. Cotterell, Crossmyloof, near Glasgow. Producing metallic designs, etc., on glass, porcelain, earthenware, plastic surfaces, metals, and other materials. February 3

1597 A. Lurashi, London. Improvements in the manufacture of articles of glass, and means or apparatus employed therein. February 3

2073 G. Lazenby, London. Improvements in kilns, such kilns being applicable for bending glass, firing stained glass, tiles, potteryware, and for other purposes. February 12

COMPLETE SPECIFICATIONS ACCEPTED.

1885.

3115 G. J. Atkins. Process for decoration and treatment of glass, porcelain, metal, etc. February 23

5012 R. Clark. Machinery for battening potters' clay. Feb. 5

5020 T. Walton. Manufacture of tumblers and other articles of glass, and apparatus or machinery therefor. February 9

5130 H. Codd. Manufacture of glass bottles. February 19

1886.

70 C. D. Abel.—Communicated by F. C. Glaser. Preparation and application of drawings and pictures to earthenware articles, and other ceramic products. February 16

805 W. Jakes and W. J. Kershaw. Ornamentation of glass articles and sheet or plate glass. February 19

IX.—BUILDING MATERIALS, CLAYS, MORTARS, AND CEMENTS.

APPLICATIONS.

- 1126 C. D. Alison, London. Improvements in the manufacture of cements and plasters. January 26
 1130 W. Johnson, Leeds. Improvements in the manufacture of sand-faced bricks, and in apparatus used therefor, part of such apparatus being also applicable in the manufacture of other than sand-faced bricks. January 26
 1163 H. R. Vaughan, Liverpool. Improvements in drying floors or plant for drying bricks and other like articles. January 26
 1191 R. Jenkins and J. Cox, Bexley Heath. Improvements in enamelled coloured plaster for walls and other objects. February 2
 1694 E. Ashby and A. Ashby, London. An improvement in cement kilns. Complete specification. February 3
 1642 O. Brach, Liverpool. A new or improved plastic composition applicable for use for absorbent purposes and for the manufacture of pipe bowls and the like. February 4
 1765 J. Chapman, Milverton, Somersetshire. Weather-proof tile. February 6
 1816 W. Joy, London. Improvements in the method of charging cement kilns and apparatus to be used therein. February 8
 1836 J. B. White, jun., London. Improvements in the manufacture of Portland cement. February 8
 2566 P. Bawden, London. Improvements in machinery for the manufacture of bricks and tiles. February 22

COMPLETE SPECIFICATIONS ACCEPTED.

1885.

- 2806 J. Cawley. Mineral amalgam or cement. January 29
 3897 J. H. Johnson—Communicated by J. Brandstatter. Manufacture of artificial stone. February 9
 5189 A. W. Lake—Communicated by T. Hyatt. Improvements in concrete lights. January 29
 5213 T. C. Fawcett and J. D. Fawcett. Machinery for pressing bricks, brickettes, tiles, etc. February 23
 5142 F. Ransome. Manufacture of Cement. February 16
 9151 W. Joy. Manufacture of cement. January 26

X.—METALLURGY, MINING, ETC.

APPLICATIONS.

- 1027 T. J. Greenway, Sheffield. Improvements in separating the precious metals from lead. January 23
 1040 E. Morewood, Llanelli. Improvements in coating with tin or other coating metal, sheets, plates, or pieces of iron or other metal. January 23
 1102 W. Tooth, London. An improved method of and means for extracting spelter, and in apparatus therefor, and for treating the waste products. January 25
 1342 A. K. Huntington, London. A method of annealing or tempering metallic wire or ribbon. January 29
 1140 P. Adie, Westminster. Improvements in tempering Steel. February 1
 1170 H. H. Lake, London—Communicated by La Société de Laminage du Nickel, France. Improvements relating to the recovery of Nickel from scraps of metal plated or coated therewith, chiefly designed for the manufacture of anodes for use in electro-plating. February 1
 1173 H. H. Lake, London—Communicated by La Société de Laminage du Nickel, France. Improvements relating to the covering or coating of metal with nickel or alloys thereof. February 1
 1796 T. Twynam, London. Improvements in the purification of iron and of phosphatic ferruginous slags. Feb. 6
 1827 G. A. Goodwin and W. F. How, London. Improvements in foundry ladles and crucibles. February 8
 1872 A. J. Boulton, London—Communicated by L. W. Sinsabaugh, United States. Method of reducing steel railroad rails to plate metal. Complete specification. Feb. 9
 1892 L. Grabau, London. Improvements relating to the extraction of metals from substances containing the same, by electrolysis, and to apparatus therefor. February 9
 1961 E. P. Vershave, E. C. F. Vershave, and A. F. V. M. Baron, London. Improvements in the manufacture of bronze and other alloys. February 10
 2274 H. R. Cassel, London. An improved process for coating or plating iron or steel. February 16
 2276 A. Eckardt, London. Improvements relating to the coating of metals with lead, tin, or zinc, or with alloys of these metals, and to apparatus therefor. February 16
 2402 H. H. Lake, London—Communicated by The Verein Chemischer Fabriken, Germany. Improvements relating to the recovery of tin from scraps of tinned plate. February 18
 2415 W. Thomlinson, London. The preparation of finely divided metalliferous substances for reduction or smelting. February 19
 2557 T. Fenwick, London. Improvements in electro-depositing zinc upon iron and other metals. February 22

2560 A. T. Davies, T. H. Griffiths, and D. Griffiths, London. Improvements in the manufacture of tin and other coated metal plates, and in apparatus employed therein. Feb. 22

COMPLETE SPECIFICATIONS ACCEPTED.

1885.

- 3721 W. H. Tooth and J. E. Rooker. Furnaces and apparatus employed in the manufacture and refining of iron, and the conversion of iron into steel. February 9
 3738 E. Morewood. Coating with tin,terne, or other coating metal, sheets, plates, or pieces of iron or other metal. Feb. 12
 4228 T. Bayley. Manufacturing oxide of iron and obtaining other useful products. February 12
 4478 W. E. A. Hartmann. Treating waste liquors from the manufacture of tin plates. February 23
 4581 T. Minnis and E. Ingram. Improvements in and connected with galvanising baths. January 26
 4925 L. Roberts, D. Roberts, and J. Colquhoun. Furnaces and appliances for smelting, puddling, refining, heating, or otherwise treating minerals, metals, etc. February 2
 8118 J. Y. Johnson—Communicated by E. Deligny. Process for purifying copper precipitates. February 23
 10621 J. Dixon, P. J. Blades, W. S. Douglas, D. Garlick, and W. Malcolm. Improvements in process of smelting pyrites and in the tuyeres of blast furnaces used therefor; also method and apparatus for feeding such furnaces. January 26

XI.—FATS, OILS, AND SOAP MANUFACTURE.

APPLICATIONS.

- 1026 R. Hutchinson, Glasgow. Improvements in the manufacture of lubricants. January 23
 1113 R. Park and J. E. Park, Glasgow. Improvements in the manufacture of soap. January 25
 1525 C. Fink, London. Improvements in lubricating compounds. Complete specification. February 2
 1930 A. C. Henderson, London—Communicated by M^{me}. Bandot, France. An improved process and treatment of fatty matters and fatty acids for use in the manufacture of stearic acid candles, which improvements render such matters applicable for other uses. February 10
 1939 J. Whittle, London. Improvements in and apparatus for extracting or separating oil or grease from cotton waste and similar materials. Complete specification. February 10
 2178 J. Dewrance, London. Lubricants for steam cylinders. February 15
 2241 H. F. Ihlee, London—Communicated by W. Benger & Sons, Germany. A new or improved manufacture of soap. February 16
 2177 T. Harrison, Arnside. Testing the lubricating power of oils called "lubricating oil tester." February 20

COMPLETE SPECIFICATIONS ACCEPTED.

1885.

- 3441 C. R. Huxley. Ammoniated soaps, free from oleates, and compounded to dispense with the destructive friction of the brush. February 5
 5382 A. G. Brookes—Communicated by R. Giebertmann. Distillation of glycerine, and means or apparatus employed therein. February 2
 5998 M. S. Gosling. Soap paste for cleansing woollen and other kindred fabrics. February 23

XII.—PAINTS, VARNISHES, AND RESINS.

APPLICATIONS.

- 1086 F. Wendling, London. Improvements in the manufacture of paint. January 25
 1511 E. W. McClave, London. Apparatus for distilling turpentine, and for the purification of the crude products of the distillation thereof. Complete specification. February 2
 1832 A. M. Clark, London—Communicated by O. Eyckens, France. An improved method of producing lead salts generally, and especially carbonate or oxy-carbonate of lead (whitelead). February 8
 2110 D. Swan, Glasgow. Improvements in obtaining pigments. February 17
 2482 W. Crow and W. Coley, Birmingham. A compound for coating metals, wood, stone, and other materials. February 20
 2530 W. Welch, Portsmouth. Improvements in hydraulic cements for coating iron and steel ships, vessels, buildings, and other surfaces. February 22

COMPLETE SPECIFICATION ACCEPTED.

1885.

- 3839 E. V. Gardner. Manufacture of whitelead, and apparatus employed therefor. January 26

XIII.—TANNING, LEATHER, GLUE AND SIZE.

APPLICATION.

- 2052 W. R. Earp, Liverpool. Improvements in the manufacture of leather. February 12

XIV.—AGRICULTURE, MANURES, Etc.

APPLICATIONS.

2298 A. C. Smethwick, Manchester. An improved method of and means for pressing and preserving grass and other vegetable substances. February 17

COMPLETE SPECIFICATION ACCEPTED.

1885.

4718 T. H. Selater. Combined insect destroyer and soil fertiliser. February 9

XV.—SUGAR, STARCHES, GUMS, Etc.

APPLICATIONS.

1108 A. M. Clark, London—Communicated by Wirth & Co., for J. J. Hang and C. Hoffmann, Russia. The manufacture of a substitute for caoutchouc and gutta-percha. Complete specification. January 25

1820 L. Cuisinier, Liverpool. A new or improved diastasic saccharine substance, and method of manufacturing the same. February 8

1888 W. R. Lake, London—Communicated by F. O. Matthiessen, United States. Improvements relating to filters, and apparatus connected therewith, for purifying sugar-liquor. Complete specification. February 9

1889 W. R. Lake (F. O. Matthiessen). Improvements in and relating to discharges for filtering apparatus to be used in the purification of sugar-liquor. Complete specification. February 9

1890 W. R. Lake—Communicated by E. E. Quimby, United States. Improvements in filtering apparatus for purifying sugar-liquor. Complete specification. February 9

1891 W. R. Lake—Communicated by R. C. Howes, United States. Improvements in filtering apparatus for use in the purification of sugar-liquor. Complete specification. February 9

1914 J. McClure C. Paton, London. Improvements in or connected with triple effect evaporating apparatus used in the manufacture of sugar. Complete specification. February 10

COMPLETE SPECIFICATIONS ACCEPTED.

1885.

4758 B. H. Remmers—Communicated by L. von Wagner and A. Gillitzer. Manufacture of starch, and apparatus therefor. February 19

7914 F. Wilhöft. Vulcanised soft rubber, and process of making the same. February 16

11618 W. Thompson, J. Mylne, and J. B. Allott. Apparatus for the expression of juice from the sugar-cane. February 2

15530 L. Sternberg. Extracting sugar from saccharine fluids. January 29

1886.

508 W. R. Lake—Communicated by W. T. Jebb. Manufacture of starch. February 12

XVI.—BREWING, WINES, SPIRITS, Etc.

APPLICATIONS.

1222 E. R. Southby, London. Improvements in treating malt extracts. January 27

1293 C. J. Pickthall, London. Improvements in linings for malt and other fermented liquors. January 28

1157 A. S. Tomkins and F. A. Cracknall, London. Improvements in apparatus for heating kilns for drying malt, grain, and other materials. February 1

1858 W. Palethorp, Newcastle-on-Tyne. Improvements in regulating and aerating worts and beers in brewing. February 9

1893 J. Mercer, London—Communicated by C. C. Beers, United States. Improvements relating to the purifying and maturing of spirituous and other liquors, and to apparatus therefor. February 9

2071 J. Smolik, London. Improvements in the construction of malt kilns, and in the method of and apparatus for drying malt. February 12

2107 F. Faulkner and W. Adlam, London. Improvements in apparatus for restricting or controlling convection or circulation of vesicles of vapour in heating or boiling wort in brewers' coppers, and in analogous processes. February 13

2108 F. Faulkner and W. Adlam, London. Improvements in the method of obtaining hop extract in the process of brewing beer, porter and other like liquors, and in apparatus therefor. February 13

2237 T. Bowen, London. An improved method of preserving alcoholic liquids, such as ale, porter, and the like. February 16

2316 F. Faulkner, Oldbury. Improved means of filtering cooler wort for determining rapid clarification of finished beer, and in arrangement of apparatus for the purpose. February 17

COMPLETE SPECIFICATION ACCEPTED.

1885.

4068 W. Lawrence. Manufacture of beer and malt liquors, and apparatus for treatment and preparation of materials for the same. February 9

XVII.—CHEMISTRY OF FOODS, SANITARY CHEMISTRY, DISINFECTANTS, Etc.

APPLICATIONS.

A.—CHEMISTRY OF FOODS.

1330 W. McDonnell, London. Improvements in the preservation of milk or cream, and in the manufacture of butter therefrom. January 29

1442 W. A. Murray, London. Improvements in the manufacture of butter. Complete specification. February 1

2144 B. M. Plumb and T. J. Richman, London. A process for extracting butter from milk, and for manufacturing butter. February 13

2191 W. McDonnell, London. Improvements in the means of preserving alimentary substances. February 15

2501 D. Johnson and H. G. R. Davies, London. Improvements in the means or apparatus for use in storing or preserving vegetable matters to be used as food. February 20

B.—SANITARY CHEMISTRY.

1053 G. H. Leame, London. An improved method of continuous filtration, applicable to the purification of sewage, and for other purposes. Complete specification. January 23

1076 H. Fewson, Buckingham. The treatment of mephitic vapours and noxious gases generally, but especially for the compound gases known as "sewer gas." January 25

1259 S. D. Cox and J. Cox, Bexley Heath. Improvements in the treatment of sewage. January 28

1727 W. H. Hartland, Glasgow. Improvements in purifying sewage and treating the same for the recovery of products therefrom, and in means or apparatus therefor. February 5

1792 F. Candy, London. Improvements in the preparation of materials suitable for use in the treatment of sewage and for other purposes. February 6

1793 F. Candy, London. Improvements in the manufacture of filtering media for use in the purification of liquids and gases. February 6

1840 W. Davis, Plaistow. Treating sewage by using sulphuric acid, lime, charcoal, and vacuum. February 9

2086 P. A. Maignon, London. An improved process for the softening and purification of liquids and the construction of apparatus used therewith. February 12

2175 A. M. Clark, London—Communicated by L. E. Robert, France. Improvements in filtering and purifying water. February 15

2139 F. H. Daneshell, London. A new or improved system of treatment of sewage. February 19

2517 F. Candy, London. Improvements in the manufacture of filtering materials and precipitants. February 20

C.—DISINFECTANTS.

2506 F. Hochuli, London—Communicated by E. Pollacsek and J. Elsner, France. An improved disinfecting soap. February 20

COMPLETE SPECIFICATIONS ACCEPTED.

1885.

B.—SANITARY CHEMISTRY.

1891 J. Richmond and T. Birtwistle. Improvements in furnaces for treating town and other refuse. January 29

1473 E. Langen. Method and apparatus for treating semi-liquid substances with purifying or other liquids. February 12

4332 J. W. Slater. Treatment of sewage and water polluted with organic matter. January 26

4711 H. J. Haddan—Communicated by G. Langbein. A method of disinfecting. February 16

5348 M. Nahnsen. Purifying drainage waters and sewage. February 9

6054 F. Maxwell-Lyte. Improvements in sewage purification process and those of other foul waters. February 19

XVIII.—ELECTRO-CHEMISTRY.

APPLICATIONS.

1011 A. Rettich, London. Improved construction or arrangement of dry electric battery, with regenerative and self-sustaining power. January 22

1051 J. H. Nond, London. An improved construction or formation of plates with composition for electric batteries. January 23

1150 T. J. Handford, London—Communicated by F. J. Sprague, United States. Improvements in and relating to electro-dynamic motors. January 26

1151 W. W. Popplewell, London—Communicated by F. La Otis Lathrop, J. W. Carter, and C. Fabre, United States. Improvements in galvanic batteries. Complete specification. January 26

1169 W. P. Thompson, Liverpool—Communicated by A. H. Cowles, United States. Improvements in smelting ores by means of electricity, and in apparatus or furnaces therefor. Complete specification. January 26

1161 W. P. Thompson, Liverpool—Communicated by E. H. Cowles and A. H. Cowles. A new or improved lining for the walls of electric furnaces. Complete specification. January 26

1340 G. C. Fricker, Putney. Improvements in dynamo-electric machines. January 29

1354 H. J. Allison, London—Communicated by E. M. Gardner, United States. An improved electrode for secondary batteries. Complete specification. January 30

1375 R. M. Bailey, jun., and A. Grundy, London. Improvements in galvanic batteries. January 30

1415 N. J. Contarini and T. Wrigley, London. Improvements in the construction of primary and secondary electric batteries. February 1

1493 H. J. Allison, London—Communicated by L. Voelker, United States. Improvements in dynamic-electric machines and motors. Complete specification. February 2

1513 G. Ignatief, London. Improvements in electric candles. February 2

1684 B. Weise, London. Improvements in secondary electric batteries. February 4

1892 L. Graban, London. Improvements relating to the extraction of metals from substances containing the same, by electrolysis, and to apparatus therefor. February 9

2103 H. J. Haddon, London—Communicated by E. H. Cowles and A. H. Cowles, United States. Improvements for operating electric smelting furnaces. Complete specification. February 18

2133 T. A. Garrett, London. Improvements in and connected with dynamo-electric machines or motors. February 19

COMPLETE SPECIFICATIONS ACCEPTED.

1885.

3467 A. M. Clark—Communicated by L. Vissière. Dynamo-electric machines. February 9

3524 T. J. Handford—Communicated by F. J. Sprague. Improvements in electric dynamic motors, parts of which improvements are applicable to the regulation of dynamo-electric generators. February 12

3599 A. Reckenzaun. Electro-motors or dynamo-electric machines. January 26

3761 J. Macnab and D. Hickie. Electric fuses. February 23

3815 H. Woodward. Thermo-electric generators and insulating materials. February 12

4127 J. S. Williams. Transforming, distributing, controlling and utilising electric and magnetic force; and apparatus or means employed therefor or in combination therewith. February 19

5202 A. Sebanschiff. Galvanic batteries. February 19

5828 B. J. B. Mills—Communicated by J. J. C. Smith. Mode of vulcanising the insulating covering of electrical conductors. February 16

7461 A. R. Upward and C. W. Pridham. Galvanic batteries. February 23

XIX.—PAPER, PASTEBOARD, ETC.

APPLICATIONS.

1061 G. F. Redfern, London—Communicated by J. Ubertin, Corsica. An improved liquid or lye to be employed in the manufacture of paper. January 13

1178 J. H. Oberhaeush, London. Improvements in the manufacture or treatment of paper for drawing or writing upon. January 26

THE JOURNAL OF THE Society of Chemical Industry:

A MONTHLY RECORD

FOR ALL INTERESTED IN CHEMICAL MANUFACTURES.

No. 3.—VOL. V.

MARCH 29, 1886.

Non-Members 50 - per annum; Members
21 - per Set; Single Copies 2s.

The Society of Chemical Industry.

Past Presidents:

Sir H. E. Roscoe, M.P., LL.D., V.P.R.S.	1881-1882.
Sir Frederick Abel, C.B., D.C.L., F.R.S.	1882-1883.
Walter Weldon, F.R.S.	1883-1884.
W. H. Perkin, Ph.D., F.R.S.	1884-1885.

COUNCIL FOR YEAR ENDING JULY, 1886.

President: F. K. Muspratt.

Vice-Presidents:

Sir F. A. Abel, C.B., D.C.L., F.R.S.	Peter Griess, Ph.D., F.R.S.
Sir I. Lowthian Bell, Bart., F.R.S.	W. H. Perkin, Ph.D., F.R.S.
Alexander M. Chance.	Sir H. E. Roscoe, M.P., LL.D., V.P.R.S.
Prof. James Dewar, F.R.S.	John Spiller.
James Duncan.	E. C. C. Stanford.
David Gamble.	J. C. Stevenson, M.P.

Ordinary Members of Council:

R. Forbes Carpenter.	S. A. Sadler, Ph.D.
Henry Doulton.	Sir Bernhard Samuelson, Bart., M.P.
John Evans, D.C.L., F.R.S.	Sir Chas. Tennant, Bart., M.P.
John Levinstein.	Prof. W. A. Tilden, F.R.S.
Rudolph Messel, Ph.D.	John Williams.
R. E. K. Newlands.	
Thomas Royle.	

With Sixteen Chairmen and Secretaries of Sections.

Honorary Treasurer:

E. Rider Cook, M.P., East London Soapworks, Bow, E.

Honorary Foreign Secretary:

Ludwig Mond, 20, Avenue Road, Regent's Park, N.W.

General Secretary: Charles G. Cresswell.

Death.

H. Sugden Evans, 10 Ottawa, Canada, at New York—February 23.

ERRATUM.

Mr. J. B. Hutcheson's name was improperly spelt "Hutchinson" in the List of Members.

LIST OF MEMBERS ELECTED 23rd MARCH, 1886.

W. B. Allbright, Boston Street, Dorchester, Mass., U.S.A., oils chemist.

Herbert A. Bainbridge, Union Club, Trafalgar Square, S.W., brewer.

C. H. Bedingfield, 4, Tichborne Street, High Fields, Leicester, traveller.

J. Ferguson Bell, C.E., Stafford, gas engineer.

W. E. Benton, Littleworth House, Hednesford, Staffordshire, lecturer on mining.

Arthur E. Brown, Morden Cliff, Lewisham, S.E.

A. S. Bryce, Glenpark Oil Works, East Nelson Street, Glasgow, oil refiner.

A. S. Bryce, jun., 8, Broompark Terrace, Dennistoun, Glasgow, oil merchant.

Carl F. Claus, jun., Iceland Wharf, Old Ford, E., chemist.

G. A. Clowes, Needham Market, Suffolk, brewer and maltster.

Donald G. Crichton, c/o John Moffatt & Co., Irvine Bank, by Herberton, Queensland, and Broughty Ferry, N.B., analyst.

W. E. Dawson, Pretoria, Transvaal, South Africa, Government Analyst.

R. Steele Fletcher, Misterton, Gainsbro', Lincolnshire, analyst.

J. H. Gorman, C.E., "Dunloe," Putney, S.W.

Jno. Gray, Pentland Oil Works, Loanhead, Midlothian, chemist.

David Hamilton, Ash Bank, Shawlands, near Glasgow, oil merchant.

Claude Hollins, Radford, Nottingham, spinner.

R. W. Hood, 16, Sandwell Road, West Bromwich, oil manufacturer.

W. F. Jack, Ravensworth, Neath, Glamorganshire, chemical works manager.

Jno. Jackson, 260, Dobbie's Loan, Glasgow, lubricating oil manufacturer.

F. H. Leeds, 14, Bouverie Road, Stoke Newington, N., consulting chemist.

J. G. MacArthur, 260, Dobbie's Loan, Glasgow, lubricating oil manufacturer.

R. H. M. Murdoch, 1, Nobel's Villas, Stevenston, Ayrshire, analyst.

Wm. Oldershaw, 69, Long Row, Nottingham, chemist.

Wm. Pearson, 20, Mellor's Buildings, Exchange Street E., Liverpool, seed crusher.

W. G. Reid, Young's Oil Co., Limited, Uphall, N.B., analyst.

C. J. Shackleton, Sydney Villa, Mill Hill, Derby; and Phoenix Chemical Works, Ironbridge, Salop, chemical manufacturer.

Masachika Shimose, M.E., Insatsu Kyoku, Tokyo, Japan, chemist (note Printing Department).

R. W. Smith, The Grange, Kirkburton, near Huddersfield, manufacturing chemist.

Jas. Shipstone, jun., Woodthorpe Lodge, Sherwood, Nottingham, brewer.

Joseph Stirk, 125, Station Street, Burton-on-Trent, engineer and brewer.

G. Crosland Taylor, Thornton Hough, near Neston, Cheshire, electrician.

Chas. F. Thatcher, Gwydyr House, 559, Old Kent Road, S.E., brewer.

Walter H. Thew, 47, Castle Street, Liverpool, provision merchant.

Geo. Ward, 26, St. Saviour's Terrace, Mere Road, Leicester, chemist.

T. M. Wilkie, Nobel's Co.'s Works, Stevenston, Ayrshire, N.B., analyst.

London Section.

CHEMICAL SOCIETY'S ROOMS, BURLINGTON HOUSE.

Chairman: David Howard.

MEETINGS, SESSION 1885-86.—First Monday in each month (unless otherwise indicated).

ORDINARY MEETINGS.

First Monday in the Month, at 8 p.m.

April 5.—Professor Unwin, M.I.C.E.—"The Principles and Methods of Testing Cementing Materials." This meeting will be held in the Central Institute, City and Guilds of London Institute, Exhibition Road, South Kensington.

May 3.—A. G. Salamon, A.R.S.M., F.C.S., and W. de Vere Milnew, F.I.C.—"The Purification of Water." Messrs. Macnab and Beckett—"The Treatment of Water for Technical Purposes."

June 7.—Dr. Meymott Tidy—"Chemical Treatment of Sewage."

July.—Annual Meeting at Liverpool.

Notices of papers and communications for the meetings to be sent to the Local Secretary.

Meeting held Monday, February 1, 1886.

MR. D. HOWARD IN THE CHAIR.

NOTES ON DR. KOCH'S WATER TEST.

BY GUSTAV BISCHOF, F.C.S., F.I.C.

THE task before me this evening has been rendered comparatively easy by Dr. P. Frankland's instructive paper, read before this Section last year,* to which I am sure you listened with as much interest as I did. Fortunately, the original intention of letting my paper precede Dr. Frankland's on the same evening was, at my suggestion, abandoned, enabling me to considerably shorten my observations on the present occasion. To prevent repetitions you will please understand that in giving the outlines of Dr. Koch's test, I adhere to Dr. Frankland's description, unless otherwise stated.

PREPARATION OF NUTRITIVE GELATINE.

Dr. Koch adds 5grms. of common salt, not 1grm. to the extract from 1lb. of beef, and mixes 100grms. of gelatine with the same quantity. I have adopted these proportions, and find no difficulty in working them. As it is a matter of some moment that the gelatine should be heated as little as possible, Dr. Frankland would perhaps tell us whether he has increased the steaming of the nutritive gelatine in test-tubes to half-an-hour on each of three consecutive days, because he found Dr. Koch's time, a quarter of an hour, insufficient. No other way is as sure to sterilise test-tubes as heat; and I prefer Dr. Koch's rule of exposing them, after cleansing and plugging, for one hour to a temperature of 150° to 180° C.

STERILISATION OF BOTTLES, PIPETTES, ETC.

Dr. Frankland continues the heating of the bottles, pipettes, etc., in an air bath, to 150° to 180° C., for at least three hours. Dr. Koch's and my experience is that one hour is sufficient, counting from the moment when the thermometer in the air bath reaches 150° C. I thought at one time that this might not be so when sterilising glass plates in a metal box, but that certain minute colonies, which I observed in some cases, might be due to imperfect sterilisation of the plates. To test this a thermometer was introduced during sterilisation into the centre of the plates, and it only indicated 100° C., when the air in the bath showed 150°; the former thermometer, indeed, did not reach 150° until the heating had been continued for another 165 minutes. The glass plates were numbered several times, when sterilised in the usual way, so that those might be known which had been in the centre; but in no case could I trace a result to their imperfect sterilisation after one hour's heating.

COLLECTION OF SAMPLES OF WATER.

For plugging flasks, test-tubes, and the like, asbestos thread has, in my opinion, advantages over the time-honoured cotton-wool. The shrinking of cotton-wool stoppers on heating sometimes causes them to become dangerously loose, however tight they may have been before. The asbestos may be heated, boiled or treated with acids to any extent; and should a plug during an experiment be accidentally dropped, it is instantly rendered serviceable by holding it for a moment into a Bunsen flame. The disagreeable sticking of cotton-wool, if any of the size used in its preparation touches the side of the test-tube, etc., is avoided by the use of asbestos. As regards exclusion of microphytes,

* See ante, p. 81.

asbestos plugs are quite equal to the other, and if cuttings from asbestos cloth be unravelled, the cost is only nominal.

I have devised flasks for transport provided with an asbestos plug, as well as a glass stopper. They are Erlenmeyer's flasks (Fig. 1) with elongated necks, which are slightly contracted near their base. Into this part a glass stopper is carefully ground; the stem reaches beyond the top of the flask, and is surrounded by the asbestos plug. During sterilisation the glass stopper should not be quite closed, or the flasks are apt to fly.

FIG. 1.

The samples of water are filled into these flasks by means of a sterilised pipette, which is enclosed during transport in an outer plugged glass tube. The pipette is immersed into the water to be tested, or, when this is not practicable, the sample is received in the first instance in a small sterilised and plugged phial provided with a lip. The phials have not a flattened rim, and before allowing the water to run in, the top is wiped with the lower sterilised part of the plug. In either case, we are thus enabled to avoid wetting the upper part of the flask, and the flushing into its interior of any impurity which may adhere to the rim.

I have made several experiments with reference to the liability of samples of water to alter if kept after collection. Table I. shows two sets, A and B, in which New River water, with or without the addition of one per cent. of sewage, was kept and tested during six days. In all my experiments the sewage was filtered through paper before being added. Each of the samples was received in a separate plugged flask, until required for use. Samples A were kept at the ordinary temperature of my laboratory, from the 14th of November last, the others in an air bath between 14° and 17° C. The New River water A shows an enormous increase from day to day, amounting in the end to 14,500 times the original number of colonies. The test on the fourth day was lost, all the colonies having run into each other. Subsequently the quantity taken in testing was reduced. The entirely different behaviour of samples A with sewage is remarkable. The latter evidently set up a kind of violent fermentation, which, culminating on the second day, when the limited quantity of food present was probably exhausted, was followed by a gradual regular decrease of the total colonies, until they were on the sixth day practically the same in number as on starting, the liquefying colonies being finally about one-third, and the total colonies one-nineteenth of those in the unadulterated sample of New River water.

Experiments B were made with another set of

materials, differing probably in the food or phosphoric acid they contained, or the microphytes present. All intermediate samples were lost through the colonies running into each other. The liquefying colonies in the New River water again multiplied enormously—viz., 1600 times, against 80 times in the mixture with sewage. The total colonies increased in the New River water about 1000 times; but in the sample containing sewage only about 2½ times.

TABLE I.—COLONIES FOUND IN NEW RIVER WATER KEPT FOR SIX DAYS.

DAY.	Liquefying Colonies.	Total Colonies.	Do. after adding 1% Sewage.		
			Liquefying Colonies.	Total Colonies.	
A	1..	1	53	14	31,000
	2..	1	2,200	210	120,000
	3..	100	260,000	210	93,000
	4..	—	—	210	62,000
	5..	88	120,000	210	47,000
	6..	610	770,000	210	40,000
B	1..	5	142	178	500,000
	6..	8,000	140,000	14,000	1,300,000

EXAMINATION OF SAMPLES.

The apparatus devised by Dr. Koch for spreading the mixture of water and nutritive gelatine on a glass plate is represented by Fig. 2. The inner one of two glass dishes is completely filled with water and ice,

FIG. 2.

when a glass plate, ground on its lower side, is pushed over the inner dish. The dishes rest on a tripod with levelling screws. A bell-shaped cover on the top completes the arrangement. The glass plate which is to receive the gelatine is taken out of the metal box, in which it has been sterilised, and reversed on to the glass plate on the top of the inner dish under the bell-shaped cover. After melting the gelatine, the plug of the test-tube is removed and a proper quantity of water to be tested introduced, avoiding, as far as possible, a vertical position of the tube. The plug is temporarily replaced, whilst water and gelatine are being mixed: it is then taken out once more, and the open end of the test-tube passed through a Bunsen flame to destroy germs which may adhere to it. Finally, the bell-shaped cover is raised just enough to allow the mixture to be spread on the glass plate, where it sets in about a minute. As the area has to be measured if the colonies are too numerous to be counted all over, the gelatine should be spread in the form of a rectangle. This is facilitated by the use of glass plates with a projecting rectangle of enamel of uniform area, which should contain 80 square centimetres when 10cc. of gelatine are used. The rim of enamel prevents the running of the gelatine should the temperature during incubation rise

somewhat high. I prefer 10 to 7cc. of gelatine, on account of the larger area, which not unfrequently allows exact counting of the colonies, when they would have been too close on the smaller area.

The damp chamber used by Dr. Koch is shown in Dr. Frankland's paper, and may be obtained in Berlin for 2s. A few experiments with a 2 per cent. corrosive sublimate seal and 150 instead of 100grms. gelatine, cultivated at 25° C., showed no practical difference in the results as compared with Dr. Koch's method. The latter appears to me more convenient, because the evaporation and condensation in the other case are somewhat excessive, and may give trouble. Even with Dr. Koch's plan, it happened in a few instances that a drop of condensed moisture fell into the sample, which, of course, had to be rejected. On this account, I now cover the plate or plates with a small curved glass plate.

The damp chambers are kept at about 18° C. in a wooden air-bath, through which passes a vertical glass tube, open top and bottom, heated from underneath by means of a small Argand burner and regulator. Unless the colonies threaten to run into each other before that time, I always leave samples in the air-bath for three days. The results of samples which are incubated for a shorter or longer time cannot be strictly compared.

When counting the colonies, the incubated sample is placed on the top of a glass plate divided into square centimetres, and partially into one-ninth part of a square centimetre, resting on a dark surface. Another plate, larger than the gelatin plate, is so arranged on a hinge that it protects the latter against dust without touching it. By this arrangement one's breath is not directed on to the gelatine, otherwise spores of *Penicillium glaucum*, and perhaps other colonies, are apt to be disseminated by the breathing, contaminating the air of the laboratory. Very many colonies are counted in a number of the smaller squares, their average being calculated on the entire area of gelatine. In the same way the larger squares are made use of with few colonies; or, indeed, the colonies are counted all over the plate. A lens sliding on the top of the hinged glass plate assists in the discovery of smaller colonies. Similarly, the liquefying colonies are counted over the whole or part of the plate, the latter being held at a certain angle towards the eye over a dark surface. This divides the colonies, as a beginning, into two classes; but it must be remembered that there are slowly and rapidly liquefying colonies, some, indeed, so slow in their action that they are not recognised as such after the normal time of incubation.

It is not an uncommon error to suppose that all the microphytes contained in a sample of water develop by the culture as described. This is not so. Microphytes, which are strictly parasitic, and thrive only in the living tissue, cannot be developed. Some microphytes have to be cultivated in blood-serum or other media.

IS DR. KOCH'S TEST A QUANTITATIVE METHOD?

I now pass over to the question whether, and how far, Dr. Koch's test can lay claim to be a quantitative method. I attempted to answer this in the first instance by mixing different proportions of a sample of sewage with a comparatively pure water. However, even very small quantities of sewage render the counting of the colonies frequently difficult or impossible, whilst a single drop cannot be measured with precision, nor can we invariably rely upon its being a representative sample. Experiments with larger quantities of water, on the other hand, require very careful handling if contamination foreign to the

sewage is to be excluded; but with this restriction they give more reliable results. Again, what we have to test is unfortunately not matter in solution, but in suspension, and chemists know how difficult it is to take strictly representative samples of matter in suspension.

I submit that the figures in Table II. show the test to be sufficiently quantitative for practical purposes, at least as regards the total colonies.

TABLE II.

Added to 1cc. of New River water drops of a mixture of 99 parts of New River water and 1 part of a sample of old sewage.		COLONIES FOUND.	
		Liquefying.	Total.
1	2	590
2	10	1,800
3	9	3,100
4	13	3,400
5	18	4,100
Do. of fresh sewage—			
1	35	3,500
2	50	5,600
3	50	8,400
4	50	10,000
5	56	12,000

The liquefying colonies are less satisfactory; but we are not dealing—as mostly in analytical chemistry—with matter unalterable in quantity. Our matter is capable of self-multiplication; and, further, amongst microphytes, the same fight is going on for supremacy or existence which we find amongst the highest of animals. Dr. Koch considers it possible that bacteria of putrefaction may succeed in exterminating the *Comma bacillus*, whilst Professor Arnaldo Cantani has furnished the following instance:—A patient with a large tubercular cavity in the upper lobe of the left lung was admitted to a hospital on the 26th of April, and improved so rapidly by inhalation of a rich culture of *Bacterium termo* in gelatine, that all the symptoms had disappeared on the 1st of June of the same year, without returning. Before the treatment animals became tuberculous when inoculated with the sputum, but after it this ceased to be. Although we must wait for confirmation of such isolated cases, they show, at any rate, that the fight I have referred to is no novelty to bacteriologists. Depending upon circumstances this must result in the supremacy, more or less, of some of the colonies.

I have made, for some time, regular monthly tests of the Metropolitan water supply, which will be found in Table III.

Without entering into details, which have been explained month by month in *Engineering* and the *Journal of Gas Lighting*, I wish to express in the first instance the great satisfaction it has given me to find on the showing of those figures that our water supply, as a whole, is bacteriologically so much purer than, I venture to say, anyone would have anticipated. I will confine myself to a comparison of the figures obtained by Dr. Frankland and myself for the months ending November, 1885, for which we made parallel reports. Taking the total, we both place West Middlesex first; second, New River; and third, Kent. I then place Southwark fourth and Chelsea fifth; Dr. Frankland reversing these two figures. Of the last batch I place Grand Junction

sixth, East London seventh, and Lambeth eighth; Dr. Frankland finding East London sixth, and Grand Junction last. Considering that the almost half-a-hundred samples here embraced were taken quite independently at different times, and several in different localities, those three months certainly agree as well as any method of chemical analysis. Let me nevertheless assert emphatically that if my figures place West Middlesex first and New River next, I do not mean by this that there is any practical difference

New River water and 1 per cent. of sewage were added. All these bottles were fixed in one frame, which was alternately inverted with a jerk up and down 500 times. Each bottle was then shaken up and a portion of the liquid passed at once through a small Swedish filter into a flask for examination, the filter and flask being sterilised. I prefer this to a settling up to 48 hours, as in the latter case the absence of colonies may be due rather to subsidence than to the treatment. However, the results in the

between them. In fact, as far as I read the results at the present moment, there is not much to choose between the supply of the different companies up to December, when the colonies in the supply of two or three of them rose somewhat high, probably owing to the rains and floods then prevailing. Dr. Frankland has applied the test to show the improvement of liquids by certain treatments. The experiments in Table IV. were made somewhat differently:—

TABLE IV.

	At Starting.		After Six Weeks.	
	Liq. Col. 57.	Total Col. 4600.	Liq. Col.	Total Col.
New River Water and 1 per cent. Sewage.				
Shaken with:—				
Animal Charcoal..	0	39	89	53,600
Coke	1	11	18	92,600
Iron Filings	1	130	24	11,600
Sand	2	970	13	1,900
Spongy Iron	0	12	0	314
Wood Charcoal ..	0	16	53	22,600

The materials mentioned in the table were passed through a sieve with 8 meshes to the linear inch, the portion that passed through a sieve with 30 meshes being rejected; 100cc. of each material were introduced into a stoppered 300cc. bottle. Bottles and materials were sterilised by heat in the usual way, and after cooling, 150cc. of a mixture of

first two columns agree sufficiently with those given by Dr. Frankland to show once more the reliability of the test when applied to such experiments. The great difference which I found in the behaviour of spongy iron and iron filings is remarkable, due probably to the porosity and greater surface of the former, and to the well-known greater chemical affinity of metals which have not undergone fusion.

In the course of the discussion on Dr. Frankland's paper, reference was made to the importance of ascertaining the relative lasting purifying power of different materials, and this induced me to add the second pair of columns. After taking the samples as explained, the bottles were filled up to the mark with the 1 per cent. sewage, and the materials shaken up and left to stand for 24 hours. During six weeks 100cc. of the liquid were then daily syphoned off, another 100cc. of dilute sewage being added, mixed, etc., as above. The shaking of the frame having been finally repeated, the figures in the third and fourth columns showed that spongy iron alone was still capable of a purifying action to any great extent.

HARMLESS AND HURTFUL COLONIES.

I feel considerable diffidence as a chemist in touching upon the harmlessness and hurtfulness of microphytes, which is involved in much doubt. To begin with, the all-important question whether the living poisons have been created as such, or are modifications of harmless forms, is in a very unsettled state. I determined, as a first step, to collect whatever evidence I could about the colonies met with in testing water, which I now beg leave to lay before you.

1. The influence of a neutral cultivating medium, or rather one which is slightly alkaline, was demonstrated by cultivation in gelatine, which had not been neutralised. The result was that 1600 liquefying, or a total of 710,000 colonies were reduced to 4 liquefying or a total of 121,000 colonies when neutralisation was omitted. Under the lens the colonies in both samples appeared very much alike, but in the acid preparation they were smaller, not unfrequently irregular in shape, and generally gave the impression of not being well developed.

2. An experiment was tried with a view of ascertaining whether the germs, which are the centres of the future colonies, can be destroyed by mechanical force. Four vertical rakes, each with six teeth projecting towards the centre, were fitted into a stoneware jar, whilst in the centre a spindle revolved, having four rows of seven teeth each, projecting towards the circumference, and so arranged that the teeth of the spindle worked between those at the circumference, almost touching them. The jar was filled with a sample of water containing 1600 liquefying, or a total of 710,000 colonies per cc., and a water-tight lid having been screwed on, the spindle was made to revolve 7424 times during 10 minutes, or 12 to 13 times per second. Under these circumstances nothing appreciable was gained. This result is interesting in connection with the shaking of water with the materials (Table IV.), as it indicates that any destruction of organisms during this treatment was in all probability not due to a mechanical action.

3. The upper range of temperature at which colonies develop freely being sufficiently known, I ascertained that up to $7\frac{1}{2}^{\circ}\text{C}$, no colonies whatever were developed in a sample of New River water, with or without the addition of 1 per cent. of sewage. As the development of organisms in samples of water unquestionably similarly depends upon the temperature, this has to be taken into account when interpreting results.

4. The following table (V.) relates to an experiment made in order to inquire what effect it has upon samples of water if air be passed through it under varied conditions.

60cc. of sample A were filled into each of three flasks in the usual way. The plug was removed from one of them, and immediately an indiarubber stopper introduced, through which passed two glass tubes—one of them dipping slightly below the surface of the water, the other ending in the upper part of the flask. Stopper and glass tubes had previously been sterilised by steam. The short glass tube being connected with an aspirator, 10 litres of the laboratory air were sucked through the water, with the result that, instead of being increased the total colonies were reduced to almost one-half (B).

TABLE V.

	Liq. Col.	Total Col.
A.—New River Water	1	53
B.—10 litres of air sucked through ..	1	29
C.—Ditto from top of Winchester quart, filled to two-thirds with sewage	2	53
D.—Ditto after bubbling through the sewage	2	49

The stopper and glass tubes were then transferred to one of the remaining flasks and the inlet tube connected with a glass tube reaching into the upper part of a Winchester quart, filled to two thirds with very foul sewage. Ten litres of air being sucked through in

this way, about the same number of total colonies were found as in the untreated sample (A). The experiment was then repeated with the third sample flask, after pushing the inlet tube inside the Winchester quart two inches below the surface of the sewage. The ten litres of air had therefore in this case to bubble right through the sewage, and yet the total colonies in the sample had certainly not increased (D).

These results are the reverse of what I expected. As experiments C and D seem to exclude the suggestion that germs had been carried off from the contents of the flask in experiment A, they have apparently been destroyed by the current of air—whether by oxidation will have to be decided by further experiments. Results C and D are of some importance in connection with the pollution of water in cisterns by sewer gas. It is variously assumed that disease germs have the property of escaping with sewer gas. In this case they must behave differently to the sample experimented on, but I will not lay myself open to the suggestion that I approved of a connection between cisterns and sewer. If for no other reason, this should be rigorously avoided for the sake of the most ordinary cleanliness.

(5.) Several experiments were made to ascertain the comparative effect of keeping samples during incubation in complete darkness, instead of exposing them to diffused light.

TABLE VI.

Sample Liquid.	Cultivated in Diffused Light.		Cultivated in the Dark.

East London Water ..	20	110	6	93
Kent Water	2	26	1	16

The preceding table shows that in the dark a more or less considerable reduction took place in four out of six parallel experiments. The increase in the ease of the second sample of New River water is explained by the presence of quite an unusually large number of colonies of *Penicillium glaucum*, which thrives well in darkness. After deducting these colonies, the sample cultivated in darkness gives sixty-two total colonies, and the other seventy-four. Unfortunately it was omitted to keep a record of the colonies of *Penicillium glaucum* present in the fourth experiment, which is the only other one showing an increase when cultivated in the dark.

(6.) Allow me to call attention once more to Table I. The sample of New River water on the first day in series A might have contained once again as many total colonies, and would still have been styled "very good" by Dr. Koch. A sample containing 770,000 colonies would certainly be considered of extremely doubtful purity. Has then the New River water become a poison by being kept at a fairly low temperature for six days, in a sterilised flask, secure against aerial contamination? Sausages, pork pies, or even beefsteak pies sometime become poisonous on keeping, through the formation of an, as yet, unknown substance; but surely this does not

apply to water under the above conditions. Following the rule that samples must be tested directly after taking, the colonies on the sixth day are of no great importance for the purposes of our test; but we may ask why it should make such an enormous difference in the interpretation of results, whether a standard of the sanitary condition of water be applied a few days later or earlier, knowing, from experience, that the sanitary condition of water does not change materially within that time. Water is stored by companies, and has to be kept frequently by consumers much longer than those samples were. What are we to do with the result, if the number of colonies found were due to such storage? I have no answer; but we must try to work this out. It almost appears that what we are testing is not so much the sanitary condition of water, as the condition under which it has been kept.

Dr. Koch styles a sample of water "very good" which contains as many as 100 total colonies. I have adopted this standard from the beginning for three reasons. First, as coming from one who has had more experience with the test than anybody else; second, because the supply of such water seemed attainable, even under by no means exceptionally good conditions; and lastly, as a safeguard against unreasonable interpretation by outsiders. Nevertheless, I look upon the number of colonies as raising rather relative than absolute standards—that is to say, its strength lies in the comparison of samples which have a like history, and which have been obtained and tested under like conditions. Microphytes multiply differently, some more rapidly than others; and, relatively, harmless microphytes may have an enormous progeny, resulting in a large number of colonies, whilst more important pathogenic microphytes may multiply less rapidly, and although productive of fewer colonies, would have a much more serious bearing upon the quality of a sample of water than the former. It will, indeed, scarcely be doubted that one single cholera or typhoid germ outweighs millions of harmless microphytes, which abound everywhere.

(7.) Two gelatine plates have been prepared by me, cultivated in the usual way. One is only nutritive gelatine, which was exposed for an hour to the air of my laboratory, the other a culture of New River water; and several, if not all of the colonies on the former will be recognised on the latter. If we were to condemn ourselves to drink sterilised water only, we should be washing down from our mouth these very same germs which result from infection by air. These germs cannot be hurtful, or the human race would long ago have become extinct. Of course, everything in excess—even the most wholesome food—becomes a poison; and therefore, also, these harmless colonies. But looking at Table I., I think we may safely assume that they are harmless within a very wide range, and I therefore propose that these colonies, as a beginning, might be styled "harmless," others "doubtful," reserving the term "hurtful" only for specific germs of disease, which we may be in a position to recognise. The colonies of the ubiquitous *Penicillium glaucum*, which appear in some cases in great numbers in culture of samples, are, in my opinion, entirely, or at least practically entirely, due to infection by the air of our laboratories. These, I think, might be omitted in counting colonies.

(8.) I have attempted to gain information about harmfulness or hurtfulness of colonies in yet another way, by keeping for some months a record of several distinct colonies, with a view of ascertaining whether some of them may be associated with pure, and others with sewage polluted water, as we associate trout with a clear mountain stream, and carp with a dirty pond. Much more extended experience

will be required before conclusions can be drawn from these records. It is further worth our attention to consider whether the diminution of colonies, when cultivating in darkness, shown on Table VI., may not be made use of for facilitating the detection of pathogenic microphytes. These, undoubtedly, are capable of development in the dark, otherwise they could not develop within the animal body. In any case I do not think there can be a reasonable objection to the rule that all cultivations be made in the dark, whether or not the important result referred to may be attained.

However, Dr. Koch has told us distinctly that we are to go beyond the simple culture in nutritive gelatin on glass plates and the counting of colonies by means of a lens. We must resort to the microscope and examine the colonies. You have seen the plate with a culture of New River water. Here is another with New River water, but with one of the lowest magnifying powers of a microscope you will detect in the latter sample distinct colonies of the *Comma bacillus*, the sample of water having been infected with a pure culture of that microphyte. This would very likely have escaped an examination with the lense only, though a practised eye, even unaided, will recognise indications which are lost to a beginner.

We must go still further. Dr. Koch recently stated about the *Comma bacillus*, it must be seen under the microscope, as it grows on gelatine, and on potatoes. The proof of its identity does not lay in any single test, but in a combination of those three tests. This applies throughout to our endeavours to classify colonies when testing samples of water. If we want to define colonies we must make pure cultures of them (shown experimentally), to be further cultivated, under appropriately varied conditions, in sterilised broth or other medium. This enables us to examine the microphytes, with a high oil-immersion power and Abbe's condenser, alive in a minute drop suspended on a microscopic glass cover, or dead after evaporation of a drop of the liquid, and tinting by methyl blue, etc. The result is a set of slides, such as you have before you, of water from Lea Bridge, the river Thames, the Metropolitan water supply, or the *Comma bacillus*, all of which remain a permanent record of the test. But even there Dr. Koch's test does not end. He tells us how to search samples for living organisms by examining on a glass cover a small drop of the water, or of its residue; another drop being again dried and tinted.

Some of the experiments I have explained are, as far as I know, the first of the kind. They are capable of extension in various ways, and if they should stimulate others to follow in the same lead, or, still better, to extend research in other directions, I shall not require an apology for having taken up your time this evening.

DISCUSSION.

The CHAIRMAN said they were all agreed that even scientific chemists should confine themselves to chemistry as far as possible; but it was increasingly evident that, far more than scientific chemists, industrial chemists could not do so at all. They were constantly brought in contact with problems necessarily involving other sciences, especially biology. A more practical question than the purification of water could not be suggested. Although similar questions were cropping up everywhere, this was one of the most practical; and all scientific engineers, at any rate, were specially interested in it. No doubt it was most desirable to have water delivered as free from all organisms as possible; and anything which

could be brought forward as to the character of these organisms should not be hurriedly passed over, nor too patiently and carefully worked out. Any light which could be thrown on the really dangerous and poisonous organisms by this mode of testing would much enhance its value. At present it was only tentative; but was still perhaps the most valuable of all the methods of water testing, although still falling short of perfection.

Professor ARMSTRONG said no doubt at the present time it was most important to have the fullest possible information on the subject of water supply. It was most desirable that chemists should discuss these matters amongst themselves, and so obtain some method which would enable them to pronounce an opinion; but up to the present time they were absolutely unable to make any use whatever of this information. What was wanted was a regular comparison between this method of operation and the ordinary method, combined with a careful examination into the history of water. By this method of research, they might gradually be in a position to make some use of these operations; but at present it was most desirable that statements should not be put forward to the general public which could only have the effect of frightening them.

Dr. PERCY FRANKLAND said at that late hour of the evening, he could not venture to refer to the many notes which he had made during the reading of the paper; but he would just refer to a few points, and afterwards come back to the one Professor Armstrong had just raised, in which he certainly differed from him. He had recently had an opportunity of studying these operations in Dr. Koch's laboratory; but neither in conversation with Dr. Koch, nor in the course of his lectures, had he ever heard him put forward the standard of 100 colonies per cc. as constituting a safe and desirable water. If ever such a statement were made, he should certainly not be prepared to endorse it. It was perfectly true that taking a water in its natural condition, and finding it with less than 100 organisms one would probably be near the truth in saying that it was a pure water, and such a verdict would most likely be substantiated by chemical analysis and an inquiry into the origin of the water; but to make a general declaration that water containing less than 100 organisms, be they what they might, was safe was not at all desirable. With regard to the details of the process, they differed in no essential way from his own. Dr. Koch's arrangement with the ice-plate was exceedingly convenient, and he now adopted it himself, as it enabled him to do in the course of an hour what formerly took a whole day. But, on the other hand, it must be borne in mind that the process of transferring from the frozen plate to the dishes might introduce a few colonies from the air—notably the *Penicillium glaucum*. It must be borne in mind that there were two difficulties to contend with—viz., the introduction of aerial organisms, on the one hand, and the destruction of organisms in the water on the other. By the use of the ice-plate some atmospheric organisms would generally gain access, whilst by the use of mercuric chloride, although aerial contamination was wholly obviated, there was a danger that some of the organisms in the water might be destroyed; on this account he no longer used mercuric chloride, but preferred simply to employ sterilised water instead. With regard to Mr. Bischof's practice of keeping the plates incubating for three days only, he was not satisfied that this was the best mode of procedure. At the best, a certain fraction of the total number of organisms present developed; and the object was to develop as many as possible. The plates, therefore, ought to stand until the colonies which appeared

threatened to merge one into the other; so that the water which contained a great number of organisms must of necessity be incubated for a shorter space of time than one which had a smaller number. This was the practice now followed in Dr. Koch's laboratory. This, however, was only a matter of detail; and the results were, on the whole, in very fair accord with his own. With regard to the development of organisms in gelatine-peptone, he did not think Mr. Bischof had quite done justice to the developing power of this substance. This mixture which he had mentioned was really one of the best developing media they were acquainted with, and was well fitted for the development of most pathogenic organisms—those of cholera, typhoid fever, erysipelas, pneumonia and diphtheria, all grew in this gelatine. As regarded its being a quantitative process, this had already been shown very strikingly. A case had come before him that day where three samples of the same water gave as the result of three different plates 4889, 4527, and 4603 colonies. With regard to shaking-up experiments, he confessed he was much surprised that, without subsidence, they had come out as favourably as they had. In the results he obtained on shaking up with coke and various other substances, the materials were allowed to subside; his idea being that the particles carried down with them in subsidence the organisms present. Then, with regard to the pathogenic and non-pathogenic microphytes, this was perhaps not the place to discuss the old question of spontaneous generation. They knew there must have been spontaneous generation at some time in the history of the world; but there was absolutely no evidence that this took place at the present day, and positively no satisfactory evidence existed that pathogenic organisms had been developed from non-pathogenic ones. This was the whole tendency of recent biological and pathological research. The experiment of development in acid gelatine presented a certain interest if the acidity of the human stomach were imitated in the gelatine; but it must be remembered as a matter of fact that there was scarcely any pathogenic organism which, in the condition of the fully developed organism, could stand the acidity of the stomach. In the condition of spores, however, they could; and if they passed the stomach in the spore stage, and got into the alkaline medium present in the intestine, they had all the facilities there for growth, and the production of their virulent properties. He need only again refer to the classical *Comma bacillus*. This organism was destroyed with the greatest facility by acid liquids. Hydrochloric acid in a dilute form was immediately fatal to the bacillus. This bacillus was not known to form spores—at least, Dr. Koch had never been able to obtain spores from it; but if it were introduced into the stomach of an animal in which an alkaline reaction had been induced, then the *Comma bacillus* entered the intestine, and multiplied and produced the characteristic disease. With regard to the air experiments, he confessed he was not surprised at the result. It was quite a familiar phenomenon to see smoke of various kinds bubbling through water without being absorbed, and, in the same way, these exceedingly fine suspended particles were not caught by the water at all. They did not come in contact with it; there was a repulsion between them and the water. The case of sewer gas was somewhat different; and he did not think a generalisation from this experiment to the case of sewer gas ought to be allowed to pass unchallenged. It must be remembered that sewer gas was not only gas, but it bore liquid particles with it. These liquid particles were carried by the gas from the sewer, in which a process of fermentation was going on. Now these liquid particles con-

tained micro-organisms, and on coming in contact with water in a cistern, for instance, they would be rapidly absorbed, because not being dry, there was no repulsion between them and the water, and they would become incorporated with it. Lastly, he came to the point of what was the use of publishing the results obtained by this process with the London waters. What had been the object of water engineers hitherto in filtering water, and in erecting expensive filter-beds? Had they intended to diminish the chemical impurities in water? Chemical analysis showed that they reduced them very slightly indeed. Did they design the filters to remove the particles of mud, clay, and so forth, which the rivers carried down with them? If they had done it for this purpose, they had acted on a very wasteful principle, because these substances were harmless. They had done this because there had been an innate feeling that there was something invisible in water which might be detrimental to health; and they had carried on these filtering operations at great cost, and had performed them with ever-increasing care, although they had had little encouragement given to them. The results obtained by Mr. Bischof and himself, in comparing the number of micro-organisms in the unfiltered waters of the Thames and Lee with the waters after filtration by the Water Companies showed distinctly that the improvement which took place in the filtering process was most remarkable. No one had ever thought such a thing possible before. The improvement chemically was almost *nil*; but the improvement from the biological point of view was most striking. He had now carried on these examinations by means of the gelatine process for upwards of a year; at frequent intervals, he had also examined the unfiltered waters; and the reduction that took place in the number of micro-organisms during filtration amounted to 95 or even 98 per cent.; in some cases the reduction was very much greater, but this was the average. He could only say that far from these results which Mr. Bischof and himself had published being of an alarmist nature, they were of an entirely opposite character, and ought to reassure the public that this process of sand-filtration, which had hitherto been regarded by most authorities on water supply as only of little value, was really an exceedingly important process in rendering river water more fit for domestic use.

Mr. FLETCHER asked if Mr. Bischof had tried passing sterilised air through the affected water to see whether the oxygenating action of the air was not acting in its favour—that is to say, when he drew air charged with organisms through the water, possibly the oxygenating action of the air counteracted the evil action of the organisms which he drew with it.

Mr. NEWLANDS asked if the animal charcoal employed was new animal charcoal with all the salts in it, or in a common working condition, so as to yield the best possible results—for instance, had it been at work in a sugar refinery for two or three months. With regard also to the coke, it would be useful to know the size, and whether it was finely divided, in which case he knew, from personal experience, it would take out a vastly greater amount of organic matter and mineral matters than when in a rough state. It would also be important to know whether the coke was an average sample. The same with regard to other materials employed—the iron filings, and the spongy iron and sand—were they fine or rough?

Mr. BISCHOF, in reply, apart from what Dr. Frankland had urged, maintained that it was of the utmost importance that different experimentalists should be able to compare results, as without this no progress

could be made; and how could they compare results if they kept the results in their note-books? If Dr. Frankland would favour him with a call, he would show him that, in his remarks on the subject of this water test, Dr. Koch stated of a sample in which he found 100 total colonies, that this was "very good."

Dr. P. FRANKLAND said perhaps he knew the origin of the water.

Mr. BISCHOF said he was very much afraid that factor could not be taken into account. The history, of course, must be taken into account; but the origin, whether it were deep well or river water, did not make much difference if it contained a certain number of colonies. He thought Dr. Frankland would also find that certain pathogenic microphytes could not be cultivated at all. As to the air bubbles not being in contact with the water, surely it must be remembered that the circumference of these bubbles was in contact; and it would be strange if some organisms were not carried with the air, especially when they knew how easy it was, as had been shown by Professor Tyndall, to purify air simply by moistening a glass dish with glycerine and leaving it for an hour, when it was found that all the germs adhered to the sides. With regard to the difference which Dr. Frankland had referred to, of sewer air containing liquid particles, he would point out that the moisture also contained liquid particles. He had not passed sterilised air in this way through a sample, because his object was to get an infection. He had tried in all possible ways to get a sample infected, and had not, therefore passed sterilised air through it; but he intended to extend his experiments very largely, and he would try this experiment. With respect to the condition of the materials, he had stated in the paper that they were all passed through a sieve of thirty meshes to the linear inch, and, therefore, the physical conditions were the same throughout; none of the materials were selected. He simply took the samples at random. They might have been fair or unfair in one case or the other; but he thought it was the fairest way to take them in their ordinary condition. The animal charcoal was in the same state as that in which it was purchased.

—♦♦♦♦♦♦♦♦♦♦—

Meeting held Monday, March 1, 1886.

MR. DAVID HOWARD IN THE CHAIR.

ON VISCOSIMETRY, OR VISCOMETRY.

BY ROBERTON REDWOOD, F.L.C., F.C.S.

IT is my intention this evening to treat the subject of viscosimetry, or the determination of viscosity, as related to the valuation of oils intended for the lubrication of machinery, and I make no apology for the selection of the subject, since the testing of viscosity is an operation which the practical chemist is frequently called upon to perform.

The introduction and rapidly increasing employment of mineral lubricating oils as substitutes for the fixed oils previously employed, have given an importance to the accurate determination of the viscosity, or body, of lubricating oils, which did not previously exist. Different samples of any given fixed oil, such as sperm oil or rape oil, vary in viscosity only within comparatively narrow limits, at a given temperature, and an engineer accustomed to use a fixed oil would in purchasing such oil derive little advantage from a knowledge of the viscosity of the sample. On the other hand, mineral lubricating oils may be manufactured of any required viscosity within limits which are wide, and it therefore follows, that having com-

menced the use of a mineral oil which affords satisfactory results, it is in the highest degree important that the engineer should be able to ascertain whether further supplies of this class of lubricant are of a viscosity similar to that of the oil already employed.

When mineral lubricating oils first came into general use it was assumed that the viscosity bore some tolerably definite relation to density; and accordingly the specific gravity of the oil was regarded as a fairly satisfactory test of its suitability. It is only within recent years that it has become recognised that the specific gravity of an oil is a worthless test of its lubricating properties; since an artificial mixture of comparatively light and comparatively heavy hydrocarbons may have the same density as the natural mixture of hydrocarbons composing a good lubricating oil, and yet be deficient in the properties of a satisfactory lubricant.

In order fully to realise, however, the importance of the determination of viscosity in mineral lubricating oils, and the value of a good test of viscosity, it will be necessary for us briefly to consider the laws of the friction of fluids, as applicable to the circumstances under which liquids are employed in the lubrication of machinery.

These laws, as is well known, differ very materially from those which govern the friction of solids, though it is important to bear in mind that the friction in the case of the lubricated rubbing surfaces of machinery in motion is usually a compound friction made up of the friction of solids, and of the friction of fluids in proportions varying according to the circumstances of the case.

The friction of solids in motion is of two kinds—viz., sliding friction and rolling friction. It is, however, only the former class of solid friction which now demands our attention. In sliding friction the magnitude of the resistance is, up to the point of abrasion, dependent upon the character of the surfaces, and proportional to the force with which they are pressed together, though in the case of lubricated surfaces the resistance may be principally due to the adhesion when the pressure is very low. In fluid friction, on the other hand, whether of liquids or gases, the resistance is proportional to the area and velocity of the surface exhibiting it, and to the density and viscosity of the liquid. As Professor Thurston* expresses it: "Fluid friction is therefore the friction of adjacent bodies of fluid in relative motion, and is due to the formation of small whirls or large eddies in the two bodies, the production of which absorbs energy from the flowing mass. The friction of the fluid finally extinguishes this energy of eddy-motion, converting it into heat, and raising the temperature of the mass by the introduction of the heat equivalent of the mechanical energy thus destroyed. The resisting property which thus effects this conversion, and which is the cause of fluid friction, is termed viscosity. . . . In the case of limpid liquids and gases the resistance is of a kinetic character, rather than one due to intra-molecular action; but the flow of viscous liquids is evidently greatly influenced by their molecular constitution."

In most cases, as I have said, the friction of the lubricated surfaces of machinery is a compound one, but in some instances it is found practicable to float the moving part in the lubricant, and under such circumstances the resistance is due only to fluid friction. On the other hand, in the case of slowly moving heavy machinery the resistance is usually largely made up by the friction of solids.

It follows from what has been said, that in theoretically perfect lubrication the resistance would be independent of the pressure, and the nearer we can approach to this condition in practice the better.

The more viscous the lubricant and the stronger the attraction taking and holding it between the moving surfaces, the greater the pressure which can be sustained; but unnecessarily high viscosity creates unnecessary fluid friction, and the viscosity of the lubricant should therefore be in proportion to the pressure. In other words, the lubricant should have only just sufficient viscosity to keep the moving surfaces apart, under the maximum pressure.

The amount of viscosity required in a lubricant, therefore, varies according to the circumstances under which the lubricant is to be used. It is obviously dependent not only upon the load carried upon a given area, but also upon the fit of the bearing surfaces, and upon the character of the motion. Thus, the axles of railway trucks are subjected to pressures greatly in excess of the load carried, when the vehicle is passing over inequalities in the permanent way. It has also been found that the power required to drive machinery which has been lubricated with an oil sufficiently viscous to keep the moving surfaces apart, is diminished when a more fluid lubricant is substituted.† It is true that this diminution of resistance is accompanied with greater wear of the metallic surfaces, and greater expenditure of the lubricant, but in the case of factories provided with insufficient motive power it may be preferable to have less theoretically perfect lubrication.‡ In a cotton mill, for instance, the use on the spindles of a very slightly better, in the sense of a more viscous, lubricant, though increasing the fluid friction between the bearing surfaces of each spindle only to an infinitesimal extent, might arrest the motion of the whole machinery of the mill.

Largely for these reasons, no doubt, the many ingenious machines of Ingram and Stapfer, Thurston, Woodbury and others, designed to test the lubricating value of oils, have not hitherto given results of much practical value. With some of these machines strictly comparative data of lubricating power under the conditions present in the machine can be obtained; but as these conditions frequently differ from those presented in actual practice, the deductions drawn from the data may be misleading.

Professor Thurston himself admits that the use of the testing machine to determine the relative friction reducing power and wear, and the endurance of oils, as data for use in the solution of the commercial problem, will often be found to involve some difficulties. These difficulties arise, however, not from faults of the method, but, as he says, from the exceedingly great uncertainty often existing as to whether the conditions of test are precisely those of use. He adds that a good testing-machine may be relied upon, if properly handled, to give accurate data; but it can rarely be made equally certain that the same conditions can be permanently retained when the lubricant is put in service. Satisfactory approximations may, however, in his opinion, readily be secured, with careful supervision and ordinary skill, for all

† It has been well said that many an engineer wastes tons of coal in an attempt to save gallons of oil.

‡ Mr. Thurston points out that the measure of the co-efficient of friction alone is not always a gauge of the value of an oil. A low co-efficient is sometimes found to co-exist with serious wear, and even low friction and a cool journal may be accompanied by wear. With very light pressures and high speeds, as with fast-running spindles, light mineral oils sometimes give low friction, and yet produce rapid wear. Mr. F. W. Arvine found that a cotton spindle, after running for some time at a speed of 6500 revolutions per minute with a fluid oil, lost as much as one-tenth gramme in weight.

* "A Treatise on Friction and Lost Work in Machinery and Millwork." By Robert H. Thurston, A.M., C.E. John Wiley & Sons, New York, 1885.

cases in which the machinery is well proportioned, in good order, and well cared for. Mr. Thurston further remarks that experiments made upon the nicely fitted journal of a testing machine are not conclusive as to suitability of a lubricant for use on a similar journal which is not well fitted. The latter bearing only in spots, or along lines of contact, is subjected on such surfaces of contact to pressure which may be enormously heavier than that affecting the same journal when wear or refitting has given it a good fitting, and the best lubricant is therefore one adapted to such intense pressure. Could the magnitude of this extraordinary pressure be known, a good testing machine would determine which of any collection of oils is best fitted to sustain it. The testing machine determines the behaviour of oils upon its own journals; if those on which the lubricant is to be used are similar, its behaviour will then be the same. While the machine does not usually serve to select oils for badly made surfaces, it exhibits the intrinsic qualities of the oils tested; and every mechanic and engineer endeavours to get all journals into as good condition as those of the testing machine, and thus fit them to do good work with good oils. Mr. Thurston also expresses the opinion that in order to determine precisely what oils are adapted to any special purpose, or to ascertain for what use any oil is best fitted, it is necessary to make an examination of the lubricant while it is working under the specified conditions. That is to say, the oil should be put upon a journal of the character of that on which it is proposed to use it, and subjecting it to the pressure proposed, running it at the speed that the journal is expected to attain: its behaviour will then show conclusively its adaptability to such an application.

I am indebted to Professor H. B. Nason, of the Rensselaer Polytechnic, Troy, State of New York, for sending me some valuable papers on the subject of the testing of lubricating oils by Professor Ordway and Mr. C. J. H. Woodbury.* The experiments conducted by Professor Ordway, in association with Mr. Atkinson, had for their object to determine, among other points, the extent to which spindle oils in common use were liable to spontaneous combustion when absorbed by cotton-waste or other similar material, as well as the temperature at which they evolved inflammable vapour. But I have referred to the investigation chiefly because these gentlemen report that three machines—two American and one English—which they had obtained with the view of testing the lubricating power of the oils under examination, furnished no satisfactory results; and it was accordingly found necessary to substitute for these machines an ordinary spinning frame, with a thermometer applied to each spindle, the heat evolved being regarded as a measure of the friction. Mr. Woodbury's papers are largely devoted to a description of the results obtained with the well-known testing machine of which he is the inventor. In the first paper it was pointed out that friction varies with the area, because the adhesiveness of the lubricant is proportional to the area, and the resistance due to this cause is a larger fraction of the total mechanical effect with light, than it is with heavy pressures. Accordingly, as the results of the preliminary work indicated that the coefficient of friction varied with all the circumstances, it was found necessary to simulate the conditions of specific

practical applications to determine the value of a lubricant for such purposes.† In Mr. Woodbury's second paper the results obtained with a modified form of apparatus constructed to carry pressures up to 40lb. per square inch were given. The experimental data contributed by Mr. Woodbury, supplemented by those reported by Mr. Beauchamp Tower in this country, constitute a comprehensive series, since Mr. Tower operated at great pressures (100lb. to 625lb. per square inch), though with a special method of lubrication (the oil-bath system); but in the discussion which followed the reading of Mr. Woodbury's second contribution, it was pointed out by Mr. F. W. Arvine, chemist of the Thompson and Bedford Company of New York, manufacturers of lubricating oil, that the agreement between the results yielded by testing machines and those obtained in actual practice was unfortunately very small.‡

As the Pennsylvania Railway Company have paid considerable attention to the testing of lubricating oils, it is instructive to find that at the end of last year the opinion of Dr. Charles B. Dudley, chemist of the company, who has studied the subject of lubricants during the past ten years, was that the problem of diminishing the loss due to friction was complicated, and not well understood.

I have not had the opportunity of working with the machine of Professor Thurston or that of Mr. Woodbury, but some years ago I was engaged for many months in testing lubricating oils with the Ingram and Stapfer machine, and I found it impossible to obtain any results that were thoroughly satisfactory from a practical point of view.

In studying the records of the experiments made in the testing of lubricating oils with the various machines which have been devised for the purpose, I have admired the ingenuity and patience with which the results were arrived at. It must, however, be obvious that the indications afforded by testing machines may in the present state of our knowledge of the subject be wholly misleading, and it is this fact which has led me to attach great importance to the adoption of a good system of determining the viscosities of oils. To my mind, indeed, the most valuable result of the experiments made with testing machines has been the demonstration of the close relation which exists between viscosity and lubricating power. Professor Thurston has pointed out that this close relation is well shown in the curves on p. 124, which exhibit graphically the results obtained by Mr. Waite.§ The figures were obtained with lard oil and light paraffin oil, the full lines representing the readings obtained with the testing machine at different temperatures, multiplied by a constant, and the dotted lines the viscosity of the oil. The diminu-

† The working pressure in Mr. Woodbury's earlier experiments was 5lb. per square inch, and the speed 500 revolutions per minute, these conditions corresponding with the velocity and pressure of a Sawyer spindle running at 7600 revolutions per minute, with a band tension of 4lb. Mr. Woodbury stated that the intermittent pressure on the wrist-pin of a locomotive amounted in as much as 3000lb. per square inch. According to Professor Thurston, the maximum pressure on the crank-pins of heavy engines is 1200lb. per square inch, and under the pivots of drawbridges sometimes as much as 9000lb. per square inch.

‡ Mr. Arvine has relinquished the use of the various machines referred to, and now conducts his tests under the conditions of actual practice. When I was in New York last autumn I spent several hours in Mr. Arvine's laboratory, and noted that he used for the testing of spindle oils a frame of spindles, such as may be found in a cotton mill, and for the testing of heavier oils a railway-wagon axle, of the usual construction, capable of being loaded with the weight commonly carried. Both pieces of apparatus were driven at the ordinary speed, and were fitted with sensitive dynamometers and thermometers. An apparatus for testing cylinder and valve oils under practical conditions of temperature and pressure of steam was in course of construction.

§ These results were reported in the Proceedings of the New England Cotton Manufacturers' Association, 1880.

* Proceedings of the Semi-annual Meeting of the New England Cotton Manufacturers' Association, held at Boston, U.S.A., 30th October, 1878. Report by John M. Ordway, representing the Department of Industrial Chemistry of the Massachusetts Institute of Technology, and Edward Atkinson, representing sundry insurance companies. Transactions of the American Society of Mechanical Engineers, Nov. 1880, and Nov. 1884. "Measurements of Friction of Lubricating Oils," by C. J. H. Woodbury, of Boston, Mass., Inspector Factory Mutual Assurance Companies.

tion of viscosity with increasing temperature is a feature to which I shall have occasion to refer later. Mr. Woodbury states that within a close approximation the lubricating qualities of an oil are inversely proportional to its viscosity; that is, that the friction decreases with the cohesion of the globules of oil for each other. Although in succeeding remarks Mr. Woodbury somewhat qualifies the statement quoted, there can, I think, be little doubt that the determination of the viscosity of an oil affords the most valuable test of lubricating properties that we have at our disposal. There may be an advantage in testing the oil by using it under conditions to which it will be subjected in actual practice, but it is admittedly exceedingly difficult to determine precisely what these conditions are, especially in some cases, and still more difficult to reproduce them with certainty. On the other hand, if a certain oil has given satisfactory results under given conditions of fit, or want of fit of bearings, pressure, speed, and temperature, it may be predicted with tolerable certainty that another oil of the same nature, having a similar viscosity, will yield equally good results.

The simplest form of apparatus for the determination of viscosity consists of a glass pipette drawn out to a small orifice; such an instrument I hold in my hand. The pipette being filled to a mark on the stem with the oil to be tested, the time occupied in the flowing out of the contents, either wholly or to a

FIG. 1.

lower mark, is noted. This form of apparatus is still largely employed, the experiments being usually made in a room maintained at a temperature of 70° F. The simple pipette is, however, not adapted for use at high temperatures, and accordingly Mr. J. Veitch Wilson, Mr. W. MacIvor, Mr. D. N. Sacker, and others have proposed to surround it with a jacket containing water or other liquid, heated to the desired temperature. It is a serious objection to the pipette that the results afforded vary to some extent with the shape of the constricted portion of the tube. Two pipettes may be constructed with jets of such size that they deliver equal quantities of a given oil at a given temperature in a given time; but if the jets vary materially in form, the two instruments will not furnish concordant results with oils of greater or less viscosity than that of the oil with which they were

standardised. The fragile nature of the pipette also constitutes an objection in cases where the instrument has to be subjected to somewhat rough usage. In the jacketed forms of pipettes the column of oil is usually of considerable length, and it is difficult to maintain a uniform temperature throughout the oil during the experiment.

To the instrument employed by Mr. C. Rumble, chemist at the Battersea Works of Price's Patent Candle Company, these objections do not attach. This apparatus consists of a metallic cylinder of considerable diameter in relation to its length, provided with an agate jet, and surrounded with a water-bath. Mr. Rumble was good enough to let me have one of these viscosimeters some years ago, and I found that, although it did not possess the chief defects of the pipette, it was susceptible of considerable improvement. Thus, although great care was taken in boring the agate jet, there were marked differences between the results afforded by instruments constructed by the same maker, and professedly alike. Again, as the screw-cap, which carried the jet and formed the bottom of the oil cylinder, was provided with a leather washer the length of the column (the cylinder always being filled to overflowing), depended to some extent upon the thickness and elasticity of the washer and the force with which the cap was screwed on. Moreover, to keep the oil at a required temperature it was necessary to have the level of the liquid in the bath so high that there was danger of some of this liquid finding its way into the oil which was being tested. Finally, there was no arrangement for heating the bath, and this was a serious objection to the instrument when viscosities were required to be taken at high temperatures.

The viscometer designed by Mr. G. M. Saybolt, inspector to the Standard Oil Company of New York, is before you, and you will observe that the instrument consists essentially of an oil cylinder of large diameter surrounded by a water-bath of considerable capacity. The jet is of metal and is enclosed in a tube extending some distance below the orifice. Immediately above the jet the oil cylinder is contracted in size, and a portion is cut away on each side so as to expose an inner glass tube. At a corresponding level, glass windows are inserted in the walls of the water-bath. Round the upper part of the oil cylinder is fitted an oil-tight gallery with raised edge, and above the platform of the gallery the oil cylinder is pierced with a number of small holes. In the use of the apparatus the bath is filled with water at the desired temperature, and a cork having been inserted in the mouth of the tube enclosing the jet, the oil cylinder is filled with the oil to be tested, until overflow through the orifices referred to occurs, and the gallery is thus also partially filled. The outflow of oil through the jet is prevented by the pressure of the air enclosed in the outer tube in the space between the cork and the jet. The oil is then stirred with a thermometer, the gallery taking the overflow caused by the insertion of the instrument, and its temperature adjusted, if necessary. On withdrawing the thermometer, oil passes from the gallery into the cylinder through the orifices to replace that which had overflowed. The gallery is then emptied by means of a pipette, the length of the oil column in the cylinder thus being determined by the position of the circle of holes; the cork is withdrawn from the tube; a stop-watch concurrently started, and the operator, looking through the window in the side of the water-bath, and through the glass tube forming the lower part of the oil cylinder, notes the time at which the oil-level makes its appearance.

The Saybolt viscosimeter is not, however, as at present constructed, suitable for use at very high

temperatures, though at temperatures up to 200° F. it gives very satisfactory results.

For the determination of the viscosity of cylinder oils at 212° F., Mr. F. W. Arvine has constructed the apparatus on the table. In this instrument the oil passes to the jet through a copper tube coiled in a bath in which water is kept in a state of ebullition, and the thorough heating of the oil to the required temperature is thus insured.

Dr. Lepenan's "Leptometer," which is used to some extent on the Continent, consists, as you see, of two similar metallic cylinders, placed vertically side by side in a water-bath. Three pairs of interchangeable jets are provided, which can be placed in orifices in the stopcocks at the bases of the cylinders. Both cylinders having been filled with a standard oil, a pair of jets of such size that the oil is delivered in drops is selected, and the jets are tested by noting whether the same number of drops issue from each jet in a given time. The standard oil in one cylinder is then replaced by the oil to be tested, and the number of drops falling from the two cylinders respectively, from one coincidence of dropping to the next coincidence is noted.

The results are approximately correct when the oils are similar; but since the size of the drops varies in different oils, or with the same oil at different temperatures, and the size of the drop is therefore not necessarily a measure of the quantity of oil flowing through the orifice, this instrument does not yield comparative results with oils differing in character. Thus, to take an extreme case, I found that the number of drops of refined rape oil falling in a given time, at a certain temperature, was the same as the number of drops of a particular mineral oil, but the size of the drops of the rape oil was so much greater that 500 drops of the two oils weighed respectively 133·6 grains and 95·8 grains.

I also ascertained that of the No. 2 jets, supplied to me with the apparatus, one not only delivered rather a smaller number of drops in a given time, in the proportion of 27 to 28 (which is, I understand, within the limits of error accepted by the makers), but also formed slightly larger drops, 500 drops delivered by this jet weighing in some cases as much as 12 grains more than a similar number of drops of the same oil falling from the other jet, under precisely similar conditions.

It is evident that the rapidity of flow in the case of any of the instruments described depends to some extent upon the specific gravity of the oil. Hence an oil of high viscosity and high specific gravity compares less favourably with an oil of low viscosity and low specific gravity, than it would if both oils were judged on the basis of viscosity only. As far as I am aware the first published suggestion of an arrangement for eliminating differences due to specific gravity was made by Mr. W. P. Mason, of Troy, New York State. This gentleman described in the *Chemical News* of 31st October, 1884, an apparatus for determining viscosity, and proposed that the length of the column of the oil to be tested should be so adjusted as to be inversely proportional to the specific gravity, and should be maintained at this calculated length during the outflow of the standard quality.* Mr. Colin R. Strong, of Manchester, however, informs me that he had previously discussed with Mr. Napier, of Glasgow, the desirability of reducing the observed viscosity of an oil to a standard density, which, he thought, could best be done by calculation. Mr. Napier then prepared a sketch of an instrument, the oil cylinder of which was in two parts, connected by

a flexible tube. The upper part was supported in such a manner that it could be adjusted at any given height on a fixed scale, and its position was to be determined by the specific gravity of the oil. The movable part of the oil cylinder was provided with an overflow pipe, and by the use of a reservoir with a stopcock it was intended to produce a continuous slight overflow during the experiment, so that the oil level should be maintained at the fixed point. I am not aware that this instrument was constructed, for at this time Mr. Napier conceived the idea of taking the speed of a paddle-wheel revolving in the oil as a measure of viscosity. Through the courtesy of Mr. Strong, I am enabled to place before you the first instrument constructed by Mr. Napier on this principle. With this viscometer, although it is but roughly made, I have obtained some fairly concordant results. I have also on the table the second instrument made, as well as the latest pattern, in which, as you see, the paddle-wheel is attached to a vertical instead of a horizontal shaft, and the toothed wheels are kept above the surface of the oil.† In the last model, a jacketed vessel to maintain the oil at a required temperature, has, at my suggestion, been added. With both patterns the measure of the viscosity is the length of time occupied by the weight which drives the wheel in falling a given distance. Mr. Napier, however, proposes to add an index disc, connected with the paddle-wheel shaft, which will show the number of revolutions made by the paddle-wheel in a given time. The apparatus must be regarded as not yet having passed through the experimental stage, but I have obtained some very promising results with it, and I am of opinion that for some purposes it will be found useful. The principal objection that I see to it is, that the conditions under which the viscosity is determined are somewhat more complex than those which attach to the testing of viscosity in the ordinary manner, since we have, to a larger extent, the friction of oil against metal, as well as the unknown and variable quantity of the friction of the bearings and of the toothed wheels of the mechanism. It may, therefore, be somewhat difficult to construct a number of instruments in which the conditions of friction of fluid against metal, and metal against metal, are the same. On the other hand, oils containing solid matter (such as paraffin) in suspension can certainly be tested far more satisfactorily in such an apparatus than in an ordinary viscometer.

I may here mention that McNaught's testing machine, with which more than fifteen years ago I worked a good deal, although professedly made for the purpose of testing lubricating power, is really an instrument for measuring viscosity. The machine consists of two discs—the lower one provided with a raised edge and attached to a vertical spindle revolving in bearings; the upper one resting on a pivot. The space between the two discs having been filled with the oil to be tested, the lower disc is caused to revolve at a given speed. The upper disc is prevented from partaking of the motion of the lower disc, communicated through the oil, by a projecting pin which comes into contact with a pendulum: the extent to which the pendulum is removed from the perpendicular being the measure of the resistance of the oil.

The instrument which I lastly propose to describe is based upon the viscosimeter of Mr. Rumble. I have already pointed out the principal defects which I found this apparatus to possess, and I will now

* From a conversation I had with Professor Nason, in Troy, last autumn, I gathered that he had suggested to Mr. Mason the arrangement in question.

† A similar apparatus has been designed by Mr. E. Gordon Cockrell, of Manchester, who, while laying no claim to the idea of using a paddle-wheel, considers that he is entitled to the credit of having introduced practical improvements.

proceed to explain the modifications which I have introduced. The instrument, as you see (Fig. 2), consists of a silvered copper oil cylinder, about $1\frac{1}{4}$ in. in diameter, by about $3\frac{1}{2}$ in. in depth, furnished with an agate jet. I have somewhat increased the length of the cylinder, in order to work with the oil level some distance below the top. Instead of the cap, which forms the bottom of the cylinder, screwing in, it is a fixture; therefore, variations due to differences in the thickness of the washer are eliminated. The exterior of the agate jet and of its metal seating are made slightly conical, and the jet, having once been fixed in position, no dislodgment or leakage can occur,

agitator, which carries a thermometer to indicate the temperature of the bath, is so constructed that splashing is prevented. The oil cylinder is furnished with a stopper consisting of a small brass sphere attached to a wire, the sphere resting in a hemispherical cavity in the agate jet. A short standard, attached to the oil cylinder, carries a clip to support a thermometer in the oil. Inside the oil-cup and at a short distance from the top, is fixed a small bracket, terminating in an up-turned point. This pointed bracket forms a gauge of the height of the oil level, similar to that which is provided in Sir Frederick Abel's petroleum testing apparatus. In boring the

FIG. 2

FIG. 3.

even when the apparatus is used at high temperatures. The copper bath, which surrounds the oil cylinder, is of such depth that the level of the bath liquid can be made to coincide with the oil level without any danger of overflow, or splashing into the oil cylinder. A copper tube, closed at the lower end, projecting at an angle of 45° from the side of the bath, near the bottom, provides a means of heating the bath liquid, and by the use of a revolving agitator, the heated liquid rising from the copper tube can be uniformly distributed through the bath. The

agate jets, the greatest care is taken to make an orifice of the standard size; but very slight variations, only indicated by differences in the rate of flow of a liquid through the jet, are unavoidable, and a correction accordingly has to be made. This is effected by adjusting the position of the bracket, and therefore the length of the oil column, so that different instruments furnish concordant results.*

* The instrument, properly standardised, can be obtained of Messrs. James How & Co., 73, Farringdon Street, London.

If the jets varied greatly in respect to size of orifice, this method of correction would probably not be satisfactory, since I should then expect to find that two instruments standardised with an oil of given viscosity would not furnish concordant results with oils of much greater or much less viscosity; but the necessary amount of correction is so small that I have not in practice found that any objection attaches to the method adopted.

The instrument is supported on a tripod stand, provided with levelling screws. In the use of the apparatus, a measured quantity of oil (50cc.) is allowed to flow out. It therefore follows that in every experiment the operator starts and finishes with a column of oil of a given length; and the results may, therefore, be regarded as the average of those which would be obtained in a series of experiments, with a head of oil maintained at any number of points between the starting and finishing points. Mr. Alfred H. Allen, who has one of these viscometers in use, has, however, fitted to the top of the oil cylinder an air-tight cap, carrying a tube passing down to a point some little distance from the bottom of the cylinder, and is in this way enabled to maintain a given head of oil throughout the experiment. I have not myself experienced the need of this modification, but it may obviously be of value in certain cases, since with its adoption any given quantity of the liquid, however small, flowing out in a given time, may be taken as the measure of the viscosity, and a considerable saving of time in the testing of a viscous oil may be effected. Mr. Allen informs me that he finds the results afforded by the instrument in its original and modified forms strictly comparable.

The instrument is employed in the following manner:—The bath is filled with a suitable liquid to a height roughly corresponding with the point of the gauge in the oil-cup. Water answers well for temperatures up to 200° F., and for higher temperatures a heavy mineral oil may be used. The liquid having been brought to the required temperature, the oil to be tested previously brought to the same temperature, is poured into the inner cylinder, until the level of the liquid just reaches the point of the gauge. A narrow-necked flask, holding 50cc. to a point marked on the neck, is placed beneath the jet in a vessel containing a liquid of the same temperature as the oil. The ball valve is then raised, a stop-watch at the same time started, and the number of seconds occupied in the outflow of 50cc. noted. It is of the greatest importance that the oil cylinder should be filled exactly to the point of the gauge, and that the given temperature should be precisely maintained during the experiment, a difference of $\frac{1}{2}$ ° F. making an appreciable alteration in the viscosity of some oils. It is also essential that the oil should be quite free from dirt or other suspended matter, and from globules of water, as the jet may be otherwise partially obstructed. If the oil cylinder requires to be wiped out, paper rather than cloth should be employed, as filaments of the latter may be left adhering. When oils are being tested at temperatures much above that of the laboratory, a gas flame is applied to the copper heating tube, and the agitator kept in gentle motion throughout the experiment. At least two tests of each oil at the given temperature should be made, and if due care is exercised, the two results will be very closely concordant. In the testing of oils for the lubrication of the bearings of machinery exposed to the air, I am accustomed to determine the viscosity at the two temperatures of 70° F. and 140° F. But in the case of cylinder oils, I make the tests at 200° F. and

250° F., though with the apparatus described, viscosities can easily be determined at 300° F., or even a higher temperature. The method in which the results should be expressed admits of a good deal of discussion. In some instances it has been customary to report the number of seconds occupied in the outflow of a given quantity as the viscosity, and since there has been no recognised method of operating, the results furnished by different experts have not been in any way comparable. Water has been taken by some, and rape oil by others, as a standard liquid, and the results have been expressed in terms of the standard liquid. Water, however, possesses too little viscosity to render it a satisfactory liquid to compare a lubricating oil with, and rape oil is not of sufficiently uniform viscosity. Mr. Charles Rumble has made a number of experiments with the object of finding a suitable liquid, and has obtained the best results with glycerine of specified specific gravity. It appears to me, however, that if a certain viscosity of rape oil, as determined in the manner described, be accepted as the standard, the admittedly variable viscosity of this oil need be no bar to the adoption of rape oil as a standard, and there is a great advantage in expressing the results in terms of a liquid of well known viscosity. I have accordingly tested, with the assistance of Mr. E. Ivens Moon, a considerable number of samples of refined rape oil, with the view of ascertaining what may be considered the average viscosity of such oil. For these samples I am indebted to Mr. Edmund Dowling (Pinchin, Johnson & Co.), Mr. J. A. Fermoy, Mr. Hirsch (Copenhagen Oil Mills), Sir W. A. Rose & Co., and Messrs. Younghusband, Barnes & Co. I am of opinion, as the result of these tests, that 535, representing the number of seconds occupied by the outflow of 50cc., may be accepted as the viscosity of refined rape oil at 60° F. I may add that the viscosity of water is, under similar circumstances, 25.5. I therefore propose that the number of seconds occupied in the outflow of 50cc. of the oil under examination, should in all cases be multiplied by 100 and divided by 535. In order then to make the requisite correction for specific gravity, the result should be multiplied by the specific gravity of the oil under examination at the temperature of the experiment, and divided by 915 (the specific gravity of refined rape oil at 60° F.); the final result will thus represent the viscosity of the oil at the temperature of the experiment, as compared with that of rape oil at 60° F. I have had some doubt whether the viscosity should not be expressed in terms of rape oil (as regards viscosity and specific gravity) at the temperature of the experiment, but it is obviously much simpler and more convenient to base all results upon the viscosity and specific gravity of rape oil at 60°, and if this view is generally accepted I do not see that any practical inconvenience can arise.

The viscosity of all oils, and especially of mineral oils, is largely affected by change of temperature, and the extent to which this occurs is a point of so much importance in regard to the value of the oils as lubricants in certain cases, that determinations of viscosity should always be made at two temperatures tolerably widely separated. The variation in the extent to which different oils are affected in viscosity by changes of temperature is shown in the table of results, which I have obtained with sperm oil, refined rape oil, neatsfoot oil, and several descriptions of American and Russian mineral lubricating oils (Fig. 6). The curves which these figures form when plotted show very clearly how comparatively little sperm oil alters in viscosity, and I think that the admitted value of

this oil as a lubricant for use under very varied conditions may be largely due to the fact that the loss of viscosity on a rise of temperature is so small. I have on a previous occasion in this room remarked upon the well-known fact that Russian oils lose viscosity upon an elevation of temperature more rapidly than American oils of the same specific gravity; but I took occasion at the time to point out that with both classes of oils the diminution of viscosity is greatest

ing may vary considerably, it is evidently desirable to give the preference to an oil which varies least in viscosity within the limits of temperature to which it is likely to be subjected.

Addendum.—After the foregoing paper was handed in, Mr. Ernest G. von Glehn, of the firm of Ragosine & Co., manufacturers of Russian mineral lubricating oils, was good enough to call my attention

in the cases of the most viscous, and since the Russian oils of a given specific gravity are more viscous than the American, one would expect to find the loss in viscosity greater. In the selection or in the valuation of a lubricating oil, it seems to me that one should, if possible, ascertain the temperature at which the oil is to be used, and determine the viscosity at that temperature. If then the viscosity of an oil which has given satisfactory results under the circumstances of the case be known, a very good opinion may be formed as to the comparative value or suitability of the oil under examination. Since, however, it is impossible in a mill, for instance, to have in use the large number of different oils which would be required if this principle were strictly carried out; and since the temperature of a given bear-

ing may vary considerably, it is evidently desirable to give the preference to an oil which varies least in viscosity within the limits of temperature to which it is likely to be subjected.

to a paper by M. Salomon,* published in the *Revue Générale des Chemins de Fer*, last year, wherein an apparatus devised by M. L. Barbet, sous-chef du Laboratoire du service du Matériel et de la Traction de la Compagnie de l'Est, for testing viscosity, is described. In this apparatus, which is termed an Ixomètre, the oil under examination is caused to flow through an annular space formed by fixing an iron rod 4mm. in diameter precisely in the centre of a brass tube 5mm. in internal diameter. Increased resistance to the flow of the liquid is thus created, and it is stated

* "Note sur l'emploi comparé des huiles de colza et des huiles minérales de Pechelbrunn et du Caucaise pour le graissage du matériel roulant." Par M. Louis Salomon, ingénieur du matériel roulant de la Compagnie des Chemins de Fer de l'Est. Paris.

that the apparatus is more sensitive than an ordinary jet viscosimeter, and gives results with oils of various viscosities differing more widely than those usually obtained.

Note.—Mr. Tyrer has placed in my hands the following written comments by Mr. Maxwell Lyte, who was unable to be present at the reading of the paper:—"The apparatus described by Mr. Redwood seems extremely ingenious, so far as its description

grease or the denser petroleum oils or rosin oils, mixed with tale or plumbago. Such an apparatus will hardly do as it is for testing such lubricants, and will have to be modified somewhat for the purpose."

In reference to these remarks, I have to say that possibly a paddle-wheel viscometer might be constructed for the testing of such greases; but I am very doubtful whether any test, other than that of using the grease under the conditions of actual prac-

FIG. 4

can be followed without illustration, and it must well answer the purpose for which it is intended. It is, however, much to be desired that a good testing apparatus should be found for the cheap solid lubricants more and more coming into use, especially on the Continent, for heavy machinery, and made from

tice, could be relied upon, unless it were found, as the result of a sufficiently extended series of experiments, that there was a similar relation between the viscosity (tested in the manner suggested) and the lubricating power of such compound greases, to that which has been shown to exist in the case of oils.

DISCUSSION.

The CHAIRMAN said this was a subject of very great interest, both as a question of abstract science involving the relation of the physical properties of these bodies, whose constitution was very little understood, and as a practical question to all who had to do with running machinery. Very little had yet been

Still it would be an immense advantage if science could afford them more accurate information.

Mr. RUMBLE said it was his intention to endeavour to make a standard fluid with glycerine, but considers able doubts were thrown on its suitability, and there was a question whether glycerine from all sources had the same characteristics. The main use of gly-

FIG. 5.—TEMPERATURE IN DEGREES FAHRENHEIT.

done in it. For the most part they had to trust to the skill of an intelligent workman to decide which were the best lubricating oils, and it was wonderful how much tact and skill a workman would acquire, and how rapidly he would perceive whether a bearing was working properly, and how accurate a thermometer a finger properly applied to a bearing was.

cerine to him was that it enabled him to standardise certain flasks which were used for measuring the flow of oil. Like many others, he had found that a glass pipette was a very unsatisfactory instrument; that you could not make two alike; that when one was gone your standard became a very different one for the future, and, therefore, you could not compare

present results with past. He used a much larger flask than Mr. Redwood, because with some of the liquids he had to test, the time, even with a larger instrument, was very short, and there would be danger of inaccuracy with too small a quantity. The standard he adopted was of the same capacity as 1614 grains of water at 70° F.

Mr. CALDERWOOD had listened with great interest to this communication, the question being one of great importance to merchants, manufacturers, and consumers. He suggested that the section should appoint a committee to confer with a committee say of the Glasgow section, and possibly of the Manchester section, and endeavour to agree on a standard. Personally he was in favour of rape oil as a standard, but perhaps he was not quite unbiassed, having been accustomed to use it for 15 years.

Mr. A. H. ALLEN (Sheffield) said he had not only listened to the paper with very great pleasure, but he agreed with Mr. Redwood in nearly everything he had advanced. He had been in the habit of using one of Mr. Redwood's instruments for determining viscosities, and was fully alive to its convenience and value. He had, however, somewhat modified it, because he often wanted to determine the viscosity, not to ascertain the lubricating value, but as a test for a particular animal or vegetable oil. For such purposes, the apparatus shown was often tedious, for he did not find, as Mr. Rumble did, that

FIG. 6.

the oil flowed too quickly, but that it ran through too slowly, and one got very tired of watching it, and keeping the temperature constant. He, therefore, used an arrangement by which the oil was kept at the same level throughout the experiment. This was effected by fitting an air-tight cover to the oil cylinder, as shown in Fig. 6. The cover is perforated by two holes, one of which, A, is furnished with a tap, B, while the other was fitted with a tube screwing air-tight into it. This tube, C, is prolonged on two sides till it is in contact with the agate orifice, while the angles of the inverted V-shaped slits cut on each side terminate at a definite height above the orifice. The cylinder is completely filled with oil before commencing an experiment, the tap B closed, and the orifice opened till the oil sinks in the inner tube to the level of D. Air then bubbles in regularly at D and rises into the closed space above the oil. When this is observed to happen the oil is collected as usual. There is then a constant head

of oil, and it ran through at the same rate, instead of the first 10cc. running through at one rate, the second at a slower rate, and so on. There is no necessity, therefore, to go on until you had 50cc., because you were sure that if 10cc. took so many seconds, 50cc. would take five times as many; and you could stop the experiment when a certain weight had flowed. After all, Mr. Redwood's is an arbitrary apparatus, arbitrary as to the size of the hole drilled in the agate, the diameter of the cylinder, the height of the column of oil, and so on; and other persons not using exactly the same apparatus will get quite different results. In order for them to be concordant, everyone must use an apparatus made exactly in accord with Mr. Redwood's directions. Still, unless someone else could put forward a better apparatus, this was likely to be adopted as the standard for the future. He was not so thoroughly convinced of its advantages six months ago as he is now, and he had in fact given up some of his own ideas and adopted Mr. Redwood's. It was clear that with a metal apparatus, the diameter could be more accurately defined than in the case of glass, and an orifice drilled in agate would not be so likely to vary by corrosion as if it were in metal. He should, however, prefer the hole to be drilled in a thin plate of agate or glass, instead of a thick one; but after all, being an arbitrary apparatus, the main point is that all should be made exactly alike. He had also used an apparatus similar to the one shown with paddle-wheels, and thought it would be exceedingly useful where rapid results were required. Differences arising from specific gravity are eliminated, and when once set going it is quite constant. He congratulated Mr. Redwood on having overcome the difficulty of keeping the oil at a constant temperature by keeping it stirred, but thought the apparatus would be improved by a cover at the top to keep in the heat. He also thought he was right in adopting rape oil as the standard, though he was inclined to think a good standard might be obtained from glycerine. Pure glycerine is easily obtained, and it might be diluted to a certain density at which its viscosity was equal to that of rape oil of average quality. Such a standard glycerine would be more definite, probably, than rape oil, and could be reproduced at will, and might, therefore, be used as a means of testing the accuracy of the apparatus. Still, for practical purposes rape oil would probably be preferable, being so familiar to persons dealing in oils. He saw no objection either to taking rape oil at 60° F., though in some respects it would be preferable to take it at the same temperature as the oil to be tested. He agreed with Mr. Redwood as to the probable reason why sperm oil was so good a lubricant under so many varying conditions. For his own purposes he should prefer to take the viscosity at ordinary temperatures, rather than at elevated temperatures. Castor oil was many times as viscous as sperm oil at ordinary temperatures, but if the temperature were raised, so as to make it run through the aperture in a reasonable time, it lost the very property which was so characteristic of it.

Mr. ARCHBUTT said it appeared to him that if a scientifically accurate result were required, water, or a mixture of glycerine and water of definite specific gravity, would be a better standard than rape oil; but such absolute accuracy was not necessary, and, as had been already pointed out, it would be difficult to persuade commercial men to adopt any standard but rape oil, which had been in use for a long time. Rape oil, however, varied a good deal. He had made a number of experiments with an apparatus of the old form, but specially constructed so as keep the temperature absolutely constant, and he found the viscosity

varied from 100 to 109, whilst one or two samples went as high as 127 on the same scale. These samples were all genuine by chemical tests, and he supposed the oil which gave the high result to be summer rape, which is said to be more viscous than winter rape. If rape oil were adopted as a standard, it would be desirable to state whether summer or winter rape was intended. Again, rape oil was often mixed with other oils, and a small proportion of linseed would reduce the viscosity considerably. So that unless some reliable test for rape oil were supplied, it seemed almost impossible for every one to be able to standardise his own apparatus, which he thought very desirable. He quite agreed with the necessity for the adoption of some standard, but he thought the subject required fuller consideration. He also considered it better in all cases to compare the viscosity of an oil with that of the standard at the *same* temperature.

Mr. FORMOY said he had found great difficulty in getting a standard rape oil; the only way it was possible was to crush hand-picked seed, grown in a certain district at 60° F., and refine it exactly. A standard oil was thus produced, the viscosity of which varied but little. He had employed an apparatus somewhat similar to Mr. Redwood's for some time, but the cylinder was greatly elongated, and he used varying columns of oil according to the specific gravity; the quantity passing through in a given time being measured. Mr. Redwood proposed to compare the viscosities of various oils at different temperatures to a certain standard of rape oil at 60°; he found it necessary to compare the various oils at the temperature at which they were to be used.

Mr. JOHNSON said he should like Mr. Redwood to define what he meant by the term viscosity, and if he had determined the influence of different materials forming the vessels or apertures through which the different fluids flowed on the results obtained. He imagined it would be a very different question using an iron nozzle with mercury flowing through it, whether the nozzle were amalgamated or not; this effect of surface attraction would apply to all the forms of apparatus for determining viscosity shown with the exception of the wheel arrangement, that was evidently a determination of the degree of adhesiveness of the oil for the oil itself; the wheel collected a film of oil on its surface, and the adhesion between the film of oil on the wheel and that in the vessel was really what was determined. This was a question which ought to be determined scientifically and accurately, and unless this were done the results would be discordant. It was evident that the adhesion of the various oils under consideration would be very different with nozzles of glass, agate, iron or other metals. He thought care should be taken that the measure of viscosity should not be accepted as a means of comparison between oils of different kinds in respect to their value as lubricants, as this would be altogether wrong and misleading.

Mr. MACTEAR thought the subject ought to be further discussed. It seemed to him in any form of apparatus of that kind, if the jets varied the whole of the results would vary. If such an instrument were to be adopted at all there must be a standard instrument, from which all others should be calibrated. Rape oil would probably be adopted as the standard, but the comparison would probably require to be given at various temperatures, such as 60°, 100°, 200°, and 212°.

Mr. T. TYLER said there were several sections in the North and Midlands where this question would be of great importance, and he might write to the secretaries suggesting that the subject should be discussed, with a view to a committee being afterwards appointed to consider it.

Prof. ARMSTRONG thought the subject was hardly yet before them in such a form as to justify any very definite action being taken. Mr. Redwood had read a very interesting and important communication, but it was a subject of which comparatively few had any experience, and, unless a very influential committee were appointed capable of dealing with the subject, both from the practical and scientific point of view, and authorised to carry out a number of experiments, the result could only be, either that Mr. Redwood's apparatus would be adopted as the standard apparatus or it would not. He could not help thinking the better plan would be to let Mr. Redwood's paper stand on its own merits; anything he brought forward would of course receive the most serious attention, but there were also very important experiments which had been carried out by Mr. B. Tower, for the Mechanical Engineers, which had resulted in former views being very much modified, and unless they could take some concerted action with other bodies they might easily do more harm than good.

Mr. REDWOOD, in reply, said that his object had been to evoke a discussion which might lead ultimately to something like unanimity of opinion on this important question. He was not wedded to any particular instrument, but found that he could obtain with the apparatus he had described as being in use in his laboratory, better results than with any other he had tried. With regard to Mr. Johnson's suggestion that experiments should be made with jets of different materials, he would say that it was clearly recognised that the results afforded by all the various forms of viscosimeters were purely arbitrary, and accordingly when he spoke of an oil as having a viscosity of 50 at a given temperature, what he meant was simply that when tested in his apparatus the prescribed quantity would flow out in half the length of time occupied by average refined rape oil at 60° F., irrespective of differences due to density. An estimate of the comparative value of different oils for use as lubricants under given conditions could thus be formed. The relation of viscosity to lubricating power was a question which could only be determined by the light of practical experience, but he had quoted authorities, who were certainly unbiassed and possessed practical knowledge of the subject, in support of the view that there was a very close relation between the two characteristics.

Mr. JOHNSON asked whether this was so as between mineral oils and vegetable oils?

Mr. REDWOOD said it undoubtedly applied as between mineral oils of different densities, and to a certain extent as between mineral oils and fixed oils. As he had, however, pointed out, the principles of lubrication were not very well understood, and he had already referred to the case of sperm oil as showing that the viscosities of a fixed oil and a mineral oil were not necessarily true indications of their respective lubricating values. But he must remark that it was for the purpose of comparing one mineral oil with another mineral oil that a correct knowledge of the viscosity was so necessary. So long as engineers were accustomed to use fixed oils, the determination of viscosity was not very important, as the variation in this respect in the case of any given fixed oil was not great; but now that mineral oils had largely replaced fixed oils, the case was, as he had explained in his paper, altogether different. Mr. Allen had said that he would have preferred a jet made by drilling a hole through a thin plate of agate, but the difficulty of making a good joint constituted an objection to such an arrangement. Moreover, if the view of M. Barbet were accepted, it was desirable to increase rather than decrease the frictional surface, and, therefore, to act upon Mr. Allen's suggestion

would be a step in the wrong direction. In conclusion, he trusted that the proposal of Mr. Calderwood would be adopted, and that some step would be taken to bring about concerted action in the matter.

Meeting held Monday, March 17, 1886.

PROF. H. E. ARMSTRONG, F.R.S., IN THE CHAIR.

ICE-MAKING AND COOLING MACHINERY.

BY T. B. LIGHTFOOT, M.I.C.E., M.I.M.E.

PUTTING aside all considerations respecting the direct use of natural ice, a process which for economical reasons must ultimately give way to mechanical means, except in certain special cases, which need not be entered upon here, it may be stated that the function of all refrigerating apparatus, which work continuously, is to absorb heat at a low temperature, and reject it at a comparatively high temperature; heat energy, the amount of which is the measure of the thermal efficiency, and to a large extent of the commercial efficiency of the apparatus, having to be expended in order to enable the refrigerating or heat-absorbing medium to part with its acquired heat to bodies at normal temperature. If the absorbed heat be not thus disposed of, it is obvious that one of two things must take place—viz., either the refrigerating medium itself must be rejected, and renewed, or equalisation of temperature would ensue, and the functions of the apparatus cease.

Refrigerating machinery may be divided into three classes, depending on the properties of the heat-absorbing agents employed in them. These are—

I. Apparatus and machines in which heat is absorbed by the evaporation of a more or less volatile liquid.

II. Machines in which a gas is cooled by allowing it to expand while performing mechanical work, and is afterwards used for abstracting heat.

III. Apparatus in which heat is abstracted by the rapid liquefaction of a solid.

It will be convenient to deal with each of these classes separately.

CLASS I.—HEAT ABSTRACTED BY EVAPORATION.

Whatever be the temperature at which a liquid is vapourised, absorption of heat must take place—this, as is well known, being due to an alteration in molecular motion, which accompanies the change in physical state. The amount of heat thus acquired varies for different bodies, and varies slightly for the same body according to the pressure at which vapourisation occurs. Among other properties, this exercises an important bearing on the fitness of any particular liquid for use as a refrigerating agent. For, other things being equal, it is obvious that the greater the heat of vapourisation, the smaller the weight of liquid that must be evaporated in a given time to produce a given cooling effect, and consequently the less the energy that must be expended in order to bring the agent into a condition to enable the heat to be rejected.

The greatest amount of heat is absorbed by water, one pound of which, in changing to the state of vapour at ordinary atmospheric pressure, requires the addition of 965.7, or, say 966 thermal units. Were this the only point to be considered in the selection of a refrigerating agent, water, by reason of this high latent heat, as well as from its plentifulness, would undoubtedly be the most suitable material. But the facility with which a

liquid can be vapourised, and again liquefied under such conditions as are convenient in practice, its effect upon the materials employed in construction, its inflammability, its stability, and lastly its cost, are of equal importance; and it will be at once seen in regard to water, whose vapour tension at freezing point is only 0.088 of a pound per square inch, that its use would necessitate the maintenance of a much more perfect vacuum than can be attained with air-pumps of ordinary construction. The vapour tensions of various liquids ordinarily used for refrigerating purposes are shown graphically in Fig. 1.

The earliest system of ice making by evaporation, is that which is still practised in some of the upper provinces of India. Water is placed in shallow pans of unglazed porous earthenware, about 1½ inches deep, which are laid in pits about 2 feet in depth, partially filled with straw, and exposed in the open air at night when the atmosphere is clear and dry. Under such conditions, heat is rapidly radiated; and this, combined with the loss of heat from evaporation—which, owing to the insulation of the dry straw, can only be acquired from the water itself—so reduces the temperature that a thin film of ice is formed on the surface. The same effect was produced by Dr. Cullen in 1755, by the use of an air-pump, while in 1810 the discoveries of Leslie resulted in the construction of an apparatus, in which from 1 to 1½ pounds of ice could be made by the rapid evaporation caused by the action of a vacuum pump, in conjunction with strong sulphuric acid, for absorbing the vapour. By reducing the pressure, water was caused to boil, and as the vapour was taken up by the acid as quickly as it was formed, a rapid evaporation was produced, which ultimately effected the freezing of the water.

Vallance and Kingsford followed on the same lines, but produced no practical results; and Carré, also, many years later, brought out an apparatus for cooling liquids and making small quantities of ice for domestic purposes, in which the same principles were embodied.

In 1878, Franz Windhausen, of Berlin, who for many years had paid attention to refrigerating apparatus, patented a compound vacuum pump, by which he proposed to produce ice direct from water on a large scale, without the employment of sulphuric acid. In the same specification he described an arrangement in which sulphuric acid could be used, the acid being cooled by water during its absorption of the vapour, and afterwards concentrated, so that a fresh supply was rendered unnecessary. In 1880, this apparatus was further developed, and fresh patents taken out, and in 1881 a machine of a nominal ice-producing capacity of 15 tons per 24 hours was put to work on the premises of the Aylesbury Dairy Co., at Bayswater, being afterwards removed to Lillie Bridge, where it now is. This installation was fully described and illustrated by Carl Pieper in a paper read before the Society of Engineers in November, 1882, and by Dr. Hopkinson at the Society of Arts about the same time.

As in order to form 1 pound of ice at 32° F. from 1 pound of water at 60°, 170 thermal units must be abstracted, 1 ton of ice will require the abstraction of 380,800 units; therefore, assuming that the whole of the cooling work is done on the water, and that only vapour passes off, it is obvious that 349 pounds of water must be evaporated to make 1 ton of ice. In addition to this, however, there would be an extra amount for taking off the sensible heat of the evaporated water itself, which, entering at 60°, would pass away at 32°. According to statements made by Mr. Pieper, the total water used in Windhausen's apparatus is about 12 times the weight of ice produced, including what is required for cooling purposes.

CURVES OF VAPOUR TENSIONS

FIG. 1.--6½ INCHES.

Fuel is consumed in driving the vacuum pumps, in evaporating the absorbed water from the weak acid in the concentrator, and in driving the concentrator air-pump. The coal consumption is given at 180 pounds per ton of ice produced; but in actual work I believe this amount is considerably exceeded. Altogether the total cost of making 1 ton of opaque ice has been stated at four shillings, but this figure was arrived at when the plant was new, and when everything was, therefore, in perfect order, and I should not be surprised to learn that the cost, including a proper amount for wear and tear, very much exceeds this sum.

In addition to the machine at Lillie Bridge, others have been erected in London, but Windhausen's process has so far not met with any extended application in this country, owing no doubt to the opaque and porous condition of the ice produced, as well as to the cumbrous nature of the plant, which, with its large and delicate pumps, and the acid-concentrating apparatus, must require considerable supervision and care in working. It has been proposed to apply the machine to the cooling of brine by evaporation, the brine being afterwards used for refrigerating purposes or for making ice on the ordinary system with open moulds. The cost, however, would, in this case, be much increased, and greatly exceed that by other processes.

In 1878, James Harrison patented an improved vacuum apparatus for refrigerating liquids by their own partial evaporation, and for making ice. One form of vacuum pump proposed by Harrison is shown

FIG. 2.—SECTION OF HARRISON'S PUMP.

in section in Fig. 2. It consists of a horizontal revolving cylinder of iron, divided into compartments, which is partially filled with a non-evaporable liquid, or one which evaporates only at a temperature considerably in excess of that at which the refrigerating liquid is evaporated, and which is also chemically neutral to the vapour with which it is brought in contact. The refrigerating or ice-forming vessel from which the vapour is to be withdrawn is connected by a pipe with one end of a fixed hollow axle, on which the cylinder revolves, a continuation of the pipe rising up inside above the level of the liquid, the partitions being stopped short at one end to enable this to be done. The cylinder is rotated, so that the compartments move round mouth downwards, carrying with them the vapour with which they are charged, and compressing it to an extent measured by the distance they dip below the surface of the liquid, until, when the compartment approaches the lowest position, the compressed vapour is liberated, and rises

into a fixed hood or casing in communication with a second hollow axle on the opposite side of the cylinder to that on which the vapour enters. Through this axle the compressed vapour passes to a surface evaporative condenser, in which, by the combined action of direct cooling, and the partial evaporation of water trickling over the tubes, it is condensed, the water of condensation, along with any air, being finally discharged into the atmosphere by means of a small pump.

Mr. Harrison informs me that he can produce ice by his vacuum process on a large scale at a cost of 1 shilling per ton, but I am not aware whether this includes any allowance for depreciation and repairs. This cost, of course, applies to opaque and somewhat porous ice made by the direct evaporation of a portion of the water to be frozen. If the ice is not made direct, but is formed in moulds, subjected externally to the action of brine that has been cooled by the evaporation of a portion of its water, the cost would necessarily be greater. But the ice would then be solid and transparent, by which its value would be increased. Several attempts have been made to produce transparent ice by the direct process, but so far without success.

So far as I have been able to ascertain, the earliest suggestions to apply the continuous evaporation of a more volatile liquid than water for the production of ice and cooling of liquids was made by Vallance, in 1824. The scheme was, however, impracticable in form, and does not seem to have taken any more definite shape than the mere suggestion in the patent specification. The first really practical machine in which the continuous vaporisation and liquefaction of a volatile fluid produced the freezing or cooling of liquids was invented by Jacob Perkins, in 1834. Ether was intended to be used, but according to Sir Fred. Bramwell, the first, and I believe the only machine ever made by Perkins was put to work with a volatile liquid arising from the destructive distillation of caoutchouc. This apparatus is really the parent of all compression machines used at the present day, from which it differs indeed only in matters of constructive detail. The water to be frozen was placed in a jacketted copper pan, the jacket being partially filled with the volatile liquid, and carefully protected on the outside with non-conducting material. A pump drew off the vapour from the jacket, and delivered it compressed into a worm, around which cooling water was circulated, the pressure being such as to cause liquefaction. The liquid was collected and led back to the jacket through suitable pipes and valves to be again evaporated.

The degree of compression in such a machine is of course dependent in the temperature of the cooling water, which defines the pressure at which liquefaction will take place; and the energy expended in producing this compression, plus that due to the rise in the sensible heat of the vapour, is the measure of efficiency. Isothermal compression, even if it could be attained, is out of the question, as the temperature of the vapour must of necessity be raised above that of the cooling medium; but the less the temperature is allowed to rise above that necessary to effect the required transfer of heat, the less is the power expended. The conditions which obtain during compression in actual practice are so various that it is impossible to attempt any accurate analysis of the process which would apply generally. Excluding friction, however, the total mechanical work expended in any compression machine may be accounted for in the following way: Heat rejected during compression; heat lost by radiation and conduction after compression; heat acquired by refrigerating agent in passing through pump; work expended in discharging the

compressed vapour from the pump. Against which is to be set work done by vapour entering the pump. From this it will be seen that the condenser has not only to get rid of the heat acquired in vapourisation, but also that imparted during compression, this latter quantity being greater or less according to the vapour dealt with, and the means adopted for keeping down the temperature during the operation; while the first quantity is independent both of the kind of refrigerating agent employed, and of the nature of the compressing process.

After Jacob Perkins, no further advances seem to have been made with this class of refrigerating machine until the years 1856 and 1857, when James Harrison, whose name has already been mentioned in connection with the vacuum process, procured letters patent in this country for an apparatus of somewhat similar description to that of Perkins, but which was worked out on a larger and more practical scale. The manufacture of this apparatus was taken up by the late Mr. Siebe, whose successors, Messrs. Siebe, Gorman & Co., still construct an improved machine on Harrison's type. Fig. 3 shows one of these machines applied to the making of ice. Ether of 720 specific gravity is

second place it is found that the lower the temperature the greater are the unavoidable losses from conduction of heat and other causes. In practice, when cooling brine for ice-making, the refrigerator is worked at a vacuum of about 25 in. of mercury, which is equivalent to a boiling point of about 10° above zero F. The condenser is made in various ways. In the present case it consists of a cluster of copper tubes placed in a wood tank, through which cooling water is circulated, the tubes being fixed into distributing boxes at each end. With the cooling water available in this country, liquefaction generally occurs at a pressure of about 3 lb. per square inch above the atmosphere, but in a warm climate it may reach as much as 10 or even 12 pounds.

In the apparatus shown on the diagram the ice is made on what is known as the can or mould system, in which moulds of sheet copper or steel, suspended in a tank, are filled with the water to be frozen, and cooled externally by the circulation of brine, the moulds being removed in order to discharge the ice as soon as it is formed.

Another method is known as the cell system. In it there are no loose moulds, but the cold brine from the

FIG. 3.

the refrigerating liquid used, its latent heat of vaporisation being 165. The refrigerator is a copper vessel containing a number of solid drawn copper tubes through which the brine passes. The vessel itself is connected to the pump by suitable pipes and valves, a smaller pipe and valve admitting the liquid ether from the condenser, the valve being so adjusted as to pass the precise quantity of ether that the pump will draw off in the form of vapour at the required working pressure. This pressure it is of course necessary to regulate so as to reduce the boiling point to the degree requisite for cooling the brine to the proper temperature. The lower the temperature to which it is desired to reduce the brine, the more perfect must the vacuum be; at the same time, so long as the brine is cooled sufficiently, it is more advantageous to work at a high pressure than a low one, for in the first place the vapour is denser, and each stroke of the pump will draw off a greater weight, and therefore produce a greater abstraction of heat, and in the

refrigerator is passed through cellular walls placed some 16 inches apart, the space between each pair of cells being filled with the water to be frozen. The ice forms on the sides of the cells and gradually increases in thickness till the two opposing layers meet and join together into one large block. If desired, however, freezing may be stopped at any time before junction occurs, and the ice removed in thinner blocks. In order to produce transparent ice it is necessary that the water should be agitated during freezing, so as to permit the air set free to escape. When moulds are used this is generally done by means of arms having a vertical or horizontal movement. With cells, agitation is generally effected from the bottom. The cost of producing transparent block ice in this country on the ether system may be taken at about 6s. per ton, with good coals at 15s. a-ton, with a well-designed machine of not less than 15 tons capacity per 24 hours, driven by a compound condensing steam engine. This is

exclusive of any allowance for repairs and depreciation.

For cooling water and other liquids, ice boxes are dispensed with, the water being passed through the refrigerator and cooled direct without the intervention of brine.

Machines of somewhat similar design have been used by Tellier with methylic ether, and by Pietet with sulphur dioxide. For certain practical reasons they have never been much introduced in this country. The cost of making ice may be taken at about the same as with ether.

I will now pass to those machines in which ammonia is employed. In 1860 Carré, taking advantage of the fact that ordinary liquid ammonia, when heated, gives off an almost anhydrous vapour which was absorbed again when the temperature was reduced, brought out a simple form of ice-making apparatus, intended chiefly for domestic purposes. This apparatus consisted of two iron vessels connected at the top by a pipe. In one vessel ordinary liquid ammonia of about 7880 specific gravity was put, and to this heat was applied. The other vessel was immersed in a basin of cold water. As soon as the temperature had risen high enough to produce the required pressure, liquefaction took place in the second vessel, the evaporation being continued until sufficient ammonia, which was necessarily mixed with a certain proportion of watery vapour, had passed over. The heat was then removed, a basin of cold water being substituted for that which had been used for condensing, and which was consequently considerably heated, while cold water was applied to the vessel that had been previously heated. The action was therefore reversed. The weak liquor

FIG. 4.

from which ammonia had been driven re-absorbed it with great rapidity as its temperature was lowered, producing very rapid evaporation from the strong liquor in the second vessel, the abstraction of heat being so great that the surrounding water was converted into ice. This is the simplest form of ammonia ice apparatus. The principle was embodied by Carré in large machines, which was afterwards improved upon by Reece, and then by Stanley, whose object was to obtain a distillate of anhydrous liquid ammonia, in order to render the working continuous, and to avoid the loss of effect caused by having a quantity of water to evaporate and cool down uselessly. This was in a great degree accomplished. Pontifex and Wood introduced still further improvements, and have succeeded in bringing the absorption machine to a high state of efficiency. Their apparatus, as applied to the cooling of liquids, is shown in

Fig. 4. It consists of eight essential parts, connected together by suitable pipes and valves. These are, an ordinary boiler for generating steam (not shown in the diagram), the generator A, analyser B, condenser and rectifier C, refrigerator or cooler D, absorber E, strong liquor pumps F, and economiser G. Besides these, if the machine is applied to the manufacture of ice, there would have to be added a brine pump, with the necessary ice-making tanks; but as these are precisely similar to those described in connection with the ether machine, it will be unnecessary to refer to them further.

Assuming the apparatus to be in operation, strong ammonia liquor of about 7880 specific gravity will be drawn from the absorber by the pumps, and delivered through the economiser into the analyser at a temperature a little above the boiling point of water. The generator, which is an iron vessel heated internally by coils through which steam from the boiler is caused to circulate, is at this time full of very weak liquor, the vapour from which, at a temperature of some 260° F., passes into the analyser, where it meets the strong liquor from the absorber and heats it, driving off nearly all the ammonia in the form of vapour through the pipe at the top into the condenser, while the remaining liquor, which is nearly pure water, falls down the analyser into the generator. The ammonia vapour that passes off is necessarily mixed with some amount of steam, but this, on account of its high boiling point, compared with that of ammonia, is condensed immediately it enters the condenser, the watery particles being caught by suitable pockets in the rectifier, and run back to the analyser, while the almost anhydrous ammonia vapour passes on to the lower coils of the condenser, where it is cooled to the temperature of the cooling water, and assumes the liquid form. The refrigerator is a vessel containing coils of iron pipes, through which brine or any other liquid it is desired to cool is passed. It is in communication with the absorber, which is maintained at a low temperature by means of a circulation of water, and into which the weak liquor from the generator passes at a certain fixed rate. This cold weak liquor is ready to absorb ammonia, consequently if the anhydrous liquid be allowed to pass from the condenser to the refrigerator it will be immediately vapourised, and will pass over into the absorber and enter into solution with the weak liquor. The weak liquor being in this manner converted again into strong liquor, is now ready to be delivered back into the analyser; but as the pressure in this latter vessel, which is at a high temperature, greatly exceeds that in the absorber, which is cold, this has to be accomplished by means of pumps. In this way a constant flow is maintained, the liquor passing through the absorber drawing off the precise amount of ammonia from the refrigerator that is entering from the condenser, so preserving a constant pressure and temperature of evaporation. This is the complete cycle; but in order to prevent the loss of heat which would be caused by the weak liquor entering the absorber at a high temperature, it is passed through the vessel called the economiser, where it is brought into contact with the cold strong liquor on its way from the absorber to the analyser, the strong liquor receiving the heat which the weak liquor loses. Assuming the action of the economiser to be perfect, which of course is impossible in actual practice, it is obvious that all the heat given out by the condensation of steam in the generator coils would be found in the water issuing from the condenser, minus that portion directly lost by radiation and conduction from the vessels and pipes. The total heat expended is that required to vapourise the ammonia, and the water, which unavoidably passes off with it in the form

of steam, but which is condensed in the rectifier and returned to the analyser, plus the amount unavoidably lost.

The cost of producing clear block ice in this country with a Pontifex machine of 15 tons capacity per twenty-four hours may be taken at about 3s. 9d. per ton with good coals at 15s. per ton, exclusive of allowance for repairs and depreciation.

Another method of using ammonia as a refrigerating agent, which, though of modern origin, and only lately introduced into this country, has

& Co. A is the pump, worked by a small steam engine combined on the same frame, D the ammonia condenser, C the refrigerator, and ice tanks—of which only one set is shown. Assuming the apparatus to be charged with anhydrous ammonia, the action is as follows:—The connections being open, vapour would be passing from the refrigerator to the pump, where it would be compressed and delivered into the condenser, the liquefied ammonia passing from the bottom of the condenser back to the refrigerator. In the diagram the refrigerator is shown combined with

FIGS. 5 AND 6.—6½ INCHES.

already been largely adopted, is the compression system. In this apparatus anhydrous ammonia, which may now be obtained as a commercial article, is employed, the latent heat of vaporisation at atmospheric pressure being 900. The machine itself is of somewhat similar construction to that already described for ether, due allowance being made for differences of pressure and in the selection of material not acted upon by ammonia. Figs. 5 and 6 show plan and side elevation of a plant for producing ice on the ammonia compression system, as made by Messrs. Siebe, Gorman

the ice tanks, coils of pipes, within which the ammonia is vapourised, being placed between each row of ice cans, the intermediate spaces being filled with brine, made of calcium or magnesium chloride and water. In this way space is saved, and the heat is abstracted directly from the water to be frozen, so avoiding the losses which exist when an independent refrigerator is used.

Other things being equal, the working pressures in a compression machine are precisely similar to those in the absorption apparatus, depending, in the condenser, on the temperature of the cooling

water, and in the refrigerator, on the degree of cold to be produced. The power expended in working the machine is simply that necessary to raise the pressure and temperature of the vapour so as to cause it to liquefy at the temperature of the cooling water, and the heat carried off by the water is the heat of vapourisation liberated in liquefaction plus that acquired during compression. This latter quantity, notwithstanding that the liquefying pressure is so much greater, is less than with ether, on account of the less weight of ammonia required for a given refrigerating effect—the weights being in inverse ratio to the heats of vapourisation—that is to say, about $5\frac{1}{2}$ pounds of ether must be circulated to produce the same effect as 1 pound of ammonia. The cost of producing ice by the compression system may be taken at about the same as with the absorption apparatus. The first cost of the plant is less.

The last system which I shall deal with under this head, and that very shortly, is one in which liquefaction is brought about by a combination of mechanical compression and absorption, generally known as the binary absorption system. So far as I am aware, the earliest workers in this direction were Mort and Nicolle, of Sydney, who, in 1869, jointly patented an apparatus in which ammonia in solution with water was made to perform the part of a refrigerating agent. The apparatus consists of an evaporator or refrigerator, a pump, and an absorber. The evaporator is supplied with strong ammonia liquor, from which, by means of reduction of pressure produced by a pump, the ammonia is caused to evaporate, so abstracting heat from the liquid to be cooled. The weak liquor escapes at the bottom of the evaporator and finds its way back to the pump, where, meeting again with the ammonia vapour, they are together forced through suitable cooling vessels under sufficient pressure to cause the solution of the ammonia, the strong liquor thus formed being again passed into the evaporator. This machine, so far as I know, has only been used by the inventors. The great objection to it is that the whole of the water entering the evaporator has to be reduced in temperature, giving up its heat to the ammonia vapour, which to this extent is prevented from performing useful cooling work. In some degree, however, this is compensated by an economiser in which the strong liquor entering the evaporator is cooled by the weak liquor passing out.

In 1880, Messrs. Du Motay and Rossi produced a binary absorption machine in which they used a mixture of ordinary ether with sulphur dioxide, which they termed ethylo-sulphurous dioxide. Before deciding on the adoption of this fluid, they made numerous experiments with other combinations of ethers and alcohols, with acids, in order to take advantage of the low-liquefying pressure of some vapours, and the greater cooling power of others. They found that liquid ether possessed an absorbing power for sulphur dioxide amounting to some 300 times its volume at ordinary temperatures, while at 60° F. the tension of the vapour given off from the binary liquid was below that of the atmosphere. In working, it was found that both liquids evaporated in the refrigerator under the influence of the pump. In the condenser the pressure never exceeded ten or twelve pounds per square inch, this being sufficient to liquefy the ether, which then absorbed the sulphur dioxide. On this account a larger compressing pump is required with the binary liquid than with pure sulphur dioxide, but the steam power to drive it is less, owing to the much lower pressure necessary to produce liquefaction. I have no particulars as to the cost of making ice by this

process, but presume it must be somewhat less than that when sulphur dioxide alone is used.

The last apparatus of this kind is one which was brought out by Pictet in 1884. So far as the apparatus itself is concerned, it presents no novelty of any importance. The peculiarity lies in the liquid, which is termed "Pictet's liquid," and which consists of carbon dioxide and sulphur dioxide, formula CO_2S . The curve of vapour tensions for this liquid is shown on Fig. 1, and it is exceedingly remarkable that for temperatures above 78° F. the tensions are actually less than for pure sulphur dioxide.

CLASS II.—HEAT ABSTRACTED BY EXPANSION OF GASES WHEN PERFORMING WORK.

This subject has been dealt with by Mr. J. J. Coleman before the Glasgow Section, in a paper on "Different Methods of Producing Cold Artificially," read on the 13th of May, 1884. My remarks under this head will therefore, to a large extent, be supplementary to Mr. Coleman's paper.

The dynamical theory of gases, though now well understood by those who have given attention to the subject, is of comparatively recent origin, its full development being due to Professor Clausius. When a gas is compressed by a piston, it becomes heated, owing to the conversion of mechanical energy expended in moving the piston into thermal energy. The heat thus acquired, supposing compression to take place in a heat-proof cylinder with frictionless piston, is the precise thermal equivalent of the work expended during compression, according to the law formulated by Dr. Joule in 1845. During expansion in a heat-proof cylinder with frictionless piston the reverse action takes place, the gas losing heat in performing work, the heat thus lost being the thermal equivalent of the mechanical work performed. Compression and expansion may, however, take place without either rise or fall of temperature, provided that the heat due to the mechanical work performed is in the one case abstracted by some external body, and in the other case is supplied from some external source. This is called isothermal compression and expansion, and the laws relating to it may be expressed by saying that—

$$\frac{\text{Volume} \times \text{absolute pressure}}{\text{Absolute temperature}} = \text{Constant for each particular gas.}$$

The other method of compression and expansion is called adiabatic, and for it the following are the relations between temperature, volume and pressure, of any two points in the same curve—

$$\frac{t}{t'} = \left(\frac{v'}{v}\right)^{\gamma-1} = \left(\frac{p}{p'}\right)^{\frac{\gamma}{\gamma-1}}$$

t , v , and p being absolute temperature, volume, and absolute pressure before expansion, or after compression; t' , v' , p' , those after expansion or before compression; and γ the ratio of the specific heat under constant pressure to that with constant volume.

Neither compression nor expansion do in practice take place either adiabatically or isothermally, the actual curves lying somewhere between the two, approaching the former in quick speed unjacketted or badly jacketted compressors, and in well-protected expansion cylinders; while with slow piston speeds with internal water injection during compression, and in thin unclothed expansion cylinders, the curves may approximate very closely to the isothermal. It is obvious therefore that in order to cool air, all that is necessary is to provide a supply in a compressed form at such temperature and pressure as will give the desired reduction after expansion in the performance of work, bearing in mind that in

practice the degree of expansion is generally limited at one end by the pressure of the atmosphere, while the initial temperature before expansion is also fixed by the temperature of the water available for cooling.

Atmospheric air is, however, never dry, but always contains aqueous vapour in solution, the amount varying under climatic influences, from that required to produce saturation, to about one-fifth of that

direct proportion. With saturated air, therefore, either reduction in temperature or increase in pressure, or both combined, will cause liquefaction of a portion of the contained vapour, while, if the air be not fully saturated at first, its relative humidity is increased, until, finally, the dew point is reached, after which liquefaction would commence.

In practice, with such apparatus as I am at present dealing with, there is always liquefaction of vapour

FIG. 7.

FIG. 8.

quantity. The temperature of saturation or "dew point" varies according to the quantity of vapour in solution, the smaller the amount, the lower being the dew point.

The capacity of air for holding moisture is also affected by pressure, a diminution in volume under constant temperature reducing this capacity in

by the combined action of the pressure and cooling after compression, while during expansion the intense cold not only causes a further condensation, but immediately converts the water so produced into ice. It is necessary, therefore, to take these effects into consideration in designing air-cooling machines. A complete apparatus of the horizontal type is shown

by Figs. 7 and 8, and a vertical belt-driven machine by Fig. 9. Air enters the compressor, and passes by a pipe to the coolers, which are placed in the bed-plate, and consist of a couple of iron vessels containing Muntz metal tubes, through which water is circulated by a pump, passing in by a pipe through the tubes, and away to the compressor jacket, from whence it escapes. The vapour condensed from the air in the coolers, collects at the bottom, and is run off from time to time. In its passage through the coolers, the temperature of the air is brought down to within about 5° of that of the cooling water. The quantity of water required is about 20 gallons per 100lb. of air, but where it is of importance this amount may be reduced by altering the construction of the coolers. The cooled and dried compressed air passes by a pipe to the expansion cylinder, where it performs work on the piston, returning from 50 to 60 per cent. of the power expended in compression, and

FIG. 9.

is exhausted, cooled to from 30° to 100° below zero F., according to the size of the machine, the speed, the degree of compression, and the initial temperature of the cooling water. The difference between the power used in compression and that given off in expansion, plus the friction of the machine, must be supplied from some external source. In the diagram, a steam cylinder is shown for this purpose, and this may of course be condensing or compound, the design readily allowing either of these types to be employed. Small machines are frequently driven by a belt, as shown in Fig. 9, either from a gas-engine or some existing source of power.

In some refrigerators, the compressors, instead of being jacketted, are supplied with an internal injection of cold water. This plan, however, while it secures a lower temperature during compression, is, in my opinion, objectionable, as in many cases pure water cannot be obtained for cooling purposes, and, therefore, the air becomes contaminated. Besides

this, when nearly dry air is being used in the machine, as is generally the case when the air is drawn back into the compressor from the room or chamber in which it has been utilised, fresh moisture is taken up, and this causes a loss in effect, due to the liberation of the heat of vapourisation and liquefaction during condensation and conversion into ice. With injection also it is essential to use some sort of supplementary cooling apparatus, such as the inter-changer described in Mr. Coleman's paper, otherwise the large quantities of snow formed during expansion would be likely to occasion great trouble.

With regard to the power required in cooling air, it may be said that about seventy-five indicated horse-power will produce 40,000 cubic feet of air per hour cooled to 80° or 90° below zero Fahrenheit, under ordinary working conditions. Measured merely by abstraction of heat, this result is of course far inferior to that obtained with any of the apparatus described in the previous section. Air machines are, however, employed under conditions which render the use of other apparatus impracticable—such, for instance, as on board ship, and on land for the freezing and preservation of meat, for cooling chocolate, butterine, gelatine dry plates for photographic purposes, and in many other instances where the advantage of having a simple and compact apparatus, capable of producing dry air at a very low temperature, is found to counterbalance the extra expenditure on account of fuel.

CLASS III.—HEAT ABSORBED IN THE RAPID MELTING OF A SOLID.

The reduction of temperature which accompanies the melting of a solid, is due to the absorption of heat in changing the molecular state, and to the rapidity with which such change is effected. Freezing mixtures all depend for their action on this rapid change of state; a simple mixture of three parts of snow and four of potash causing a reduction of temperature from freezing point to 51° below zero Fahrenheit. Such a mixture is, however, inapplicable for commercial purposes, except on a small scale, and the same may be said of all those in which snow or ice is employed. Considerable depression in temperature may, however, be caused without the use of ice by dissolving certain salts in water or acid, and from time to time attempts have been made to produce ice on a practical scale by such means. Many years ago the late Sir W. Siemens made use of calcium chloride in connection with his principle of heat regeneration, which in this case was applied in a negative manner for the abstraction and rejection of heat. When crystals of calcium chloride are dissolved in water, the temperature is lowered about 30° F. With water at 60° to 65° initial temperature, this reduction is not sufficient to produce ice, and Sir William Siemens therefore devised an apparatus in which the cold could be accumulated or intensified by making use of the low temperature of the spent liquor in abstracting heat from the water to be cooled. The liquor was afterwards evaporated, and the salt recovered. I believe this apparatus worked well and produced ice, but it was abandoned by the inventor, who considered it inferior to mechanical methods employing a volatile liquid.

In the Toselli machine, which has been sold in considerable numbers, ammonium nitrate is used. This salt, when dissolved in water, reduces the temperature some 40° F. The apparatus consists of a vessel in which the solution is effected, and a multiple ice can, containing slightly tapered cylindrical moulds of various sizes. When the freezing mixture is complete, the ice can is introduced, the moulds having previously been filled with water. In a few

minutes ice is formed round the edges, to the thickness of about one-eighth of an inch. These rings are then removed, and placed one within the other, so forming a small stick of ice. The Toselli machine can only be used when a supply of water below 60° F. can be obtained.

Recently in the United States an attempt has been made to employ ammonium nitrate for the production of ice on a large scale, in a modified form of Sir William Siemens's apparatus, so as to enable a freezing temperature to be produced independently of the initial temperature of the water supply. Several forms are proposed. One of them is called a quadruplex ring machine, and is made to freeze from two to fifty pounds of ice per hour. It consists of a series of annular vessels, one within the other, containing in the centre the moulds in which ice is to be formed. The cold produced by dissolving the salt in the outer ring cools water in the second one. This again, on salt being added, cools the third, and the third the fourth, the temperature in this way being reduced sufficiently to freeze the water in the moulds. Two, three, or more rings are used according to the initial temperature of the water. No motive power is required beyond that necessary to keep the whole apparatus in motion, so as to promote the solution of the salt. I am not aware whether the system has actually been applied on a large scale, but apparatus has been designed for such an application. In this case the process would be continuous, ammonium nitrate being automatically fed into a tank, where it would be dissolved in water previously cooled by the spent liquor after it had left the ice-making tanks or cooling rooms. The fresh liquor at a low temperature would be circulated by suitable pumps, and returning through the heat-exchanging apparatus just referred to, would finally pass into an evaporating tank, where by means of heat the water would be driven off and the ammonium nitrate recovered.

No doubt such a plant could be made to work satisfactorily, but it is certain that unless most of the evaporation could be performed in the open air, without the use of fuel, it would be most expensive to work, as the amount of fuel to evaporate the whole of the water would be far greater than that required to produce the equivalent cooling effect with any of the apparatus employing a volatile liquid as the refrigerating agent.

CONCLUSION.

In concluding this somewhat lengthy paper, I must observe that it must be understood that the machines and apparatus which have been specially referred to are not the only ones of the kind. They are merely given as examples to illustrate the different systems, and have been selected by me because they are those with which I am most familiar, and because they are, in my opinion, good examples of their respective classes. The paper does not deal with mechanical details, and it is only in these that the machines of various makers differ with one another.

For assistance in the preparation of diagrams I must acknowledge my indebtedness to Messrs. Siebe, Gorman & Co., and Messrs. Pontifex & Wood.

DISCUSSION.

The CHAIRMAN said that Mr. Lightfoot's paper was peculiarly valuable, inasmuch as it was the first which had dealt with the whole subject, and being directly associated with this kind of work, his statements commanded full confidence. Probably few of the members had any idea to what extent refrigerating machinery was now used. Mr. Lightfoot's reference to Pictet's liquid was one of the most interesting

features of his paper from a scientific point of view. It showed the great importance of further investigation into the mutual relations of various volatile fluids. The discovery that a mixture of carbon dioxide and sulphur dioxide had a vapour pressure considerably below that of the less volatile was certainly a very remarkable one. It was usual to regard sulphur dioxide as simply SO₂ and carbon dioxide as CO₂, whereas Pictet's work showed distinctly that, at a considerable distance above their boiling points, and indeed above ordinary zero, the molecules of these gases must be of more complex composition.

Mr. HARRISON said that he brought out the ether machine in 1856, his attention being first drawn to the subject by the arrival in Sydney, in the year 1837, of a cargo of ice from America. Having studied chemistry under Professor Graham at the Andersonian Institute in Glasgow, he thought that it might be possible to make ice. He accordingly took two ordinary thermometers and surrounded the bulb of one with ammonia and the other with ether. The one with ammonia fell very rapidly, but the effect of the ether was more prolonged; so after working out an ammonia process something on Carré's principle, he discarded it in favour of ether, and took out his first patent in Australia. He then came to London and employed Mr. Siebe to make his first two machines, a small one and a large one. After spending £2000, and realising that the time was not ripe for ice machines in this country, he took the big machine back to Australia, and in two years drove the Americans out of the field. At that time he knew nothing of previous failures, and was not even aware of Perkins' machine until some years after he had ceased to take any part in the business. The only practical point on which he could give any information was with regard to Table I. The figures there were perfectly correct at the temperatures given, but they were to some extent delusive. The latent heat of water when evaporated at the freezing point in a vacuum was about 1100° instead of 900°; sulphuric ether when evaporated at about 20° had a latent heat of considerably more than 165°, which was the right figure at the temperature of 96°. The latent heat of ammonia, on the other hand, at the usual working temperature, was considerably less than 900°. This was rather important practically, though he could find no record of it. For practical purposes white ice was superior to clear ice, in the same way as white sugar was preferable to sugar-candy for sweetening, because it melted more quickly, and produced a more rapid effect. He had in Australia to combat the prejudice in favour of clear ice, but ultimately the white ice was preferred.

Mr. GORMAN remarked that the author of the paper had very modestly refrained from saying, with regard to the cold-air machine in the diagram, that it was his own invention. It was doing good service, and was in use for freezing meat, and more lately fish, in many parts of the world, simplicity of construction being one of its chief advantages, as there were no valves to get out of order. They were still making the ether machine, on account of its simplicity of action: it had few joints to keep sound, and worked at a low pressure, never amounting in this climate to more than 4lb. per square inch in the condenser, and in India to 11lb. when the thermometer was at 92°.

Mr. CHRISTY exhibited a sample of Japanese isinglass made from seaweed by a freezing process. Being too fine to be strained, it was frozen solid by a current of air passed through a freezing mixture, and cut into the requisite sizes. On thawing the water drained away with the impurities, leaving the mass perfectly dry and solid.

Dr. MESSEL thought that Pictet's liquid deserved more attention than it had received. The author's cold-air machine, like all mechanical refrigerators, converted only the amount of heat into mechanical energy which was added to it by the fuel used, but in Pictet's machine, using his new liquid, there was molecular work done in addition; and therefore, if Pictet's statements were correct, it ought to be the cheapest of all ice machines at present known. Of course it was possible that other liquids might have similar properties, but this was the only one known at present. Pictet's explanation was that it required less horse-power to liquefy the mixed gases than the gases separate; whilst, when gasified again, they would give up latent heat equal to that of the two gases taken independently.

Mr. LIGHTFOOT said, in reply, that he did not quite appreciate the force of Dr. Messel's remarks. Putting aside friction in all compression machines, no matter whether a gas or condensable vapour was used, the whole of the heat utilised from the fuel was converted into mechanical energy. In Pictet's new machine, as in other previous ones employing a binary liquid, no doubt the mechanical work necessary to cause liquefaction was less than if either of the two liquids was used alone, but it did not follow, as Dr. Messel had said, that "it ought to be the cheapest of all ice machines at present known." It might be so, but, from a circular he had seen, it appeared that, notwithstanding the advantage gained with the binary liquid, Pictet used about double the horse-power that was required with anhydrous ammonia. Dr. Messel was also mistaken in saying that Pictet's was the only binary liquid at present known, as at least one other had been in use for several years before Pictet's was brought out. With regard to Perkins' machine, it was only right he should say that he believed it was simply an experiment, only worked in the factory where it was constructed. There was no doubt very few people knew of its existence, and Mr. Harrison's invention, some years later, was quite independent and original. With regard to Mr. Harrison's criticisms upon the table of heats of vaporisation, he had already stated that the figures he had given were at atmospheric pressure, and would have to be modified according to the temperature. He was not aware that other determinations had been made, and should be glad if Mr. Harrison could tell him where they were to be found.

MEETINGS, SESSION 1885-86.—First Tuesday in each Month, at 7 P.M.

Notices of papers and communications for the meetings to be sent to the Local Secretary.

ERRATUM.—In the paper of Mr. Rowland Williams, appearing in the last (February) number of this Journal, page 73 and sixteen lines from bottom, after the word "and" should be inserted the words, "after decomposing with a slight excess of acid."

ON A METHOD FOR THE DETERMINATION OF THE RELATIVE STIFFNESS OF PASTE PRODUCED BY ACTING ON FLOUR OR STARCH WITH BOILING WATER

BY WILLIAM THOMSON.

Flours or starches, like others of the carbohydrates, whilst possessing similar chemical percentage composition, differ very materially from each other in their physical properties; thus, cane and beet-root sugars have precisely similar percentage chemical compositions, yet the former is much sweeter to the taste than the latter; and so with flours or starches—whilst two samples may possess the same percentage composition, the one on being mixed with boiling water might give a much thicker paste than the other, the same weights of each being employed. Calico printers and sizers take cognisance of this difference between samples of flour or starch, some preferring for their purpose those which give the thickest paste, whilst others select those for their manufacture which produce the thinnest. Upon this quality of the starch or flour much depends, and disputes often arise between buyer and seller as to the qualities of such materials in this respect. In calico printing for instance, the colour is mixed with starch paste to give it consistency, and it is evident that the starch which gives the necessary consistency with the smallest quantity of dry starch will be the most valuable for that purpose; again, in sizing yarn where it is desired to introduce the smallest possible quantity of size into the warp, the starch or flour which gives the thickest paste on being boiled with water is selected.

The method which is at present employed for testing flours and starches is to take a certain weight of the sample, place it in an ordinary sauce-pan or basin, add a measured quantity of water, and heat till the water boils; after boiling for one, two or three minutes, the paste is poured into an ordinary glass or cup and allowed to cool. The pastes are then removed from the cups by tilting them upside down, when the paste having the shape of the vessel in which it cooled is left. The relative stiffness of these pastes are then roughly judged by pressing the fingers into each, and noticing as far as possible which offers greatest resistance to the pressure of the finger. This method is unsatisfactory from several points of view: first because it is possible that the same sample of flour may be boiled at two different times by the same person, and by reason of the one having being boiled or heated before boiling for a longer time than the other, a greater amount of water may evaporate from the one than from the other, thus making considerable difference in the consistency or stiffness of the pastes each would produce. I have overcome this difficulty by making the paste in a closed vessel. At first I used ordinary stoppered bottles in which equal weights of the different samples to be tested were placed along with equal quantities of water; the bottles with their contents were then put into a tin vessel containing cold water, which was gradually heated to boiling, the bottles meanwhile being shaken from time to time. This appeared to give a satisfactory paste, which was then poured out and further examined on becoming cold. I found, however, that the paste so produced was not satisfactory, because as soon as it became thick it was impossible to mix it further by shaking the bottles, and it was difficult to pour out the paste so as to obtain an absolutely homogeneous mixture, as I found on testing the pastes afterwards by the process hereinafter mentioned. After a number of further experiments I arrived at

the following method for making the pastes. 1 part of flour, for instance, is mixed with 6 parts of cold water in a glass cylinder 12 inches long by 2 inches diameter, the mouth being firmly closed with an india-rubber cork through which passes a wire about $\frac{1}{4}$ inch diameter, terminating in a round disc formed by first bending the wire at right angles to itself, and then coiling it round itself until a circle of sufficient diameter has been formed. This disc of coiled wire acts as a plunger, being drawn up and pushed downwards by the straight piece of wire which passed airtight through the india-rubber stopper, the hole in the stopper being lubricated with castor oil. The glass cylinder has a flanged top which enables the stopper to be firmly tied down. A number of these cylinders, charged with equal weights of flour or starch, and mixed with equal volumes of water, are placed in a large vessel containing cold water sufficiently deep to nearly cover the upright cylinders. The water in this vessel is then gradually heated to boiling, the plunger being worked in each cylinder alternately during the time of heating to keep the flour and water well mixed. About five minutes after the water has reached the boiling-point the plungers are drawn to the surface, which is levelled by twisting the plunger round on the surface, and then drawing it up still further till it touches the rubber cork. The pastes are then allowed to cool and afterwards tested. The first and I believe only attempts which have been made to quantitatively determine the relative stiffness of different pastes was to place weights on the surface, and observe what weight was required to break through the surface or skin. There are two serious objections to this method: the first is, that a little more drying of the surface of one paste than another would make the one support a much heavier weight than the other, although both pastes might have been made in the same way from the same sample of flour; again, there is a surface tension on the paste, as there is on water, so that if the weight be carefully manipulated, the paste may be made to support a much heavier one than it would do if less care were used, much on the same principle as a dry sewing needle may be made to float on water if carefully placed on its surface. Further, it is somewhat difficult to get a weight having its centre of gravity in a vertical line passing through the centre of the weight, and consequently one part of the edge of the weight is likely to press on the paste more than another, the result being that the weight gradually tilts over to one side, and the edge being generally sharp cuts through the surface and the weight then embeds itself edge foremost. That this method has never proved successful in the hands of anyone, is shown by the fact that, although a quantitative method would be most valuable, no quantitative results expressing the stiffness of flour or starch pastes have ever been employed by either buyer or seller.

One method at which I worked and which at first seemed promising, was to measure the pressure of air required to force the paste through a hole of given dimensions. For this I poured different pastes in the different tests into an ordinary glass funnel, the stem of which passed airtight through a cork, and was closed by a cap of india-rubber. When the paste has cooled and set, the cap is removed from the stem of the funnel, the cork fitted into a flask, which is connected with a vacuum pump and manometer by a tube which also penetrated the cork, the pressure required to force the paste through the stem of the funnel into the flask is then read off, and although it is possible that satisfactory results may yet be obtained by some modification of this method, I had to abandon

it as unsatisfactory, the pressure required at one time to force the same paste through the stem being much greater than that required at another, for some reason or reasons which I was unable thoroughly to comprehend.

The last process I devised has given satisfactory results, and will be still further improved. It is based on the principle of allowing some body having a known momentum to enter the paste, and then to express in measurement the distance to which it penetrated the paste before coming to rest. Perhaps the most scientific method of using this principle would be to make use of an air gun, or some other appliance, to propel a bullet with precisely the same velocity into columns of paste lying horizontally, but I thought it highly improbable that a bullet of constant weight could be obtained which could be shot always at a constant velocity; besides, assuming that such conditions could be fulfilled, a still more difficult problem would be to find the bullet after it had entered the paste.

The method which I ultimately employed as the most practicable which occurred to me, was to allow a rod or spindle of iron, $\frac{1}{4}$ in. diameter and 10 in. long, sharpened pencil-like at both ends, to acquire a standard momentum by falling through a space of 12 inches, and to measure the distance to which it penetrated the paste, on falling.

The iron rod was suspended from one end by being made to adhere to one of the poles of an electro-magnet, and when the rod was hanging at rest, the magnetism was destroyed by breaking the current (produced from a small bichrome cell) by means of a switch. The moment the current is broken the spindle drops, and remains at rest embedded to a greater or less depth in the paste. The finger nail can be used as a mark of the part of the spindle which is at the surface of the paste, when it can be withdrawn and immediately measured on an ordinary rule.

If the paste be too thin, the rod may descend through it to a considerable distance before coming to rest, and the *vis viva* having been destroyed, the spindle may then sink slowly by the continued action of gravitation. It is possible under those circumstances to catch the spindle between the fingers the moment the energy produced by the fall has been expended, but when the paste is so thin as this, the results cannot be considered satisfactory. I tried some experiments by using rods of three-quarters, and of half the length of the original rod or spindle, and tried to calculate the results yielded by the one into that which would be given by the other, by use of the ordinary formula of mass and velocity of the falling body, but I found no satisfactory result could be obtained from it. The lighter the spindle the less penetrating power it had for the 12 in. fall, but it cannot be said that a paste which is penetrated by a spindle to the extent of 1 in. has twice the stiffness of another paste which the same spindle penetrates to the extent of 2 in. Doubtless the best way of making use of this process to obtain accurate results is to take a standard flour or starch, and to make it into paste simultaneously with the samples to be tested against it; and after preliminary trials of all, to increase or diminish the quantities of the samples till they are exactly equal to the standard as tested by the penetration produced by the fall of the spindle.

In making the experiment with the spindle, I take the glass jars in which the pastes were prepared, and after leaving them over-night in cold water, that the whole paste may come to the same temperature, I place each jar alternately under the electro-magnet, then take a thread to which is attached a small lead

weight. This is suspended from the centre of the pole of the magnet to which the spindle is afterwards suspended, and the jar arranged underneath that the first fall will take place about the centre of the paste; other falls can be made on to points surrounding the centre. I find it practicable to make in all about 8 tests on each paste, the mean of which I think gives a fairly satisfactory result. In my first experiments I did not place the pastes in cold water over-night, and I found the distance penetrated by the fall of the spindle into the centre was less than when it fell near the sides of the vessel; but the cause of this I found to be mainly due to a difference in the temperature, the paste in the centre being several degrees colder than that at the sides. The temperature therefore at which these experiments are made should always be accurately noted immediately after the tests have been made.

As ordinary jelly (solution of glue) is presumably more easily obtained perfectly homogeneous than flour or starch paste, because it is quite liquid when hot, I made most of my preliminary experiments in that medium, and the following results will show: *First*, that the different tests made with jellies or pastes agree reasonably closely with each other; and *Second*, that the temperature affects very materially the stiffness of either.

In determining the distance to which the spindle penetrated the jelly or paste, I took as a unit the sixteenth of an inch, so that the following numbers must be read as sixteenths of an inch as measured on the spindle—thus if the spindle penetrated 1 in., the number given would be 16; if 2 in., 32, and so on.

The same jelly was employed for each of the following experiments. When one series of experiments was made, the jelly was melted in the well-closed glass cylinders to prevent evaporation, and then cooled for the next experiment. The jelly was made by dissolving 1½ ounces of gelatine in 20 ounces of water.

Temperature of Jelly, Centigrade.	Mean of Results Obtained.	Actual Result Obtained.
9.5	43.8	43, 43, 45, 41, 41.
11.6	45.5	44, 45, 47, 46, 46, 45.
12.0	46.3	46, 47, 46.
12.1	46.2	46, 45, 48, 46, 46.
12.5	43.4	47, 49, 49, 47, 50.
14.4	63.5	68, 60, 64, 62, 65, 62, 63, 65.

The following are three samples of air-dried India corn starches. The pastes were prepared by heating at the same time 1 part of each sample with 10 parts of water. The samples Nos. 2 and 3 are by the same maker, and No. 1 by a different maker.

No.	Temperature, Centigrade.	Mean of Results Obtained.	Actual Results Obtained.
1	15.8	41.7	40, 44, 41.
2	15.8	57.4	52, 56, 60, 61, 58.
3	16.2	51.3	52, 54, 59, 55, 54.

These results will serve to show generally what the process can do; that at all events it gives reasonably concordant results for the same samples, considering the nature of the material with which we have to deal; and they are given with the hope that others

will expend some time and ingenuity in devising a still more accurate method of measuring the stiffness of different samples of flour or starch pastes—a matter which is of so much importance to calico printers, and to sizers and cotton manufacturers. I have to thank my assistant, Mr. W. H. Dawson, for the care and work he has expended over these experiments.

DISCUSSION.

Mr. GRIMSHAW thought that the author had made a distinct advance on the old rule of thumb method, although one might doubt whether buyers and sellers would adopt a plan which involved the use of an electro magnet. The results would, however, gain in accuracy if stronger pastes were used.

Mr. ESTCOURT said that an admitted defect of the process was that the depth to which the spindle penetrated was no arithmetical measure of comparison between two starch samples without going into a very abstruse calculation. If, after a preliminary test or two, Mr. Thomson were to dilute the stiffer sample until the spindle entered both to the same depth, then the quantity of starch used to make each paste would be an inversely proportional measure of their relative resistances.

Mr. THOMSON, in reply to a question put by the Chairman, said that he did not think that the stiffness produced in cloth would be proportional to the stiffness of the paste. It was very questionable whether it would not be in inverse ratio. It was generally considered that the stiffer the paste was, the more valuable it was to calico printers and others. Complaints were constantly arising in reference to farina sent from Hamburg not being up to sample, and hence it was important that some accurate method of testing should be devised. His process was capable of distinguishing, within two or three per cent., the difference between two starch pastes; but, as Mr. Estcourt had pointed out, when very accurate results were required, the sample to be tested must be assimilated to the standard paste employed by making repeated trials, and adding more or less water on each occasion. The test was as yet only a relative one, but he had brought it under the notice of the meeting in order that it might engage the attention of investigators, who would work it up into a scientific method. It was quite possible that by heating starch pastes until they boiled, stiffer pastes could be obtained than by merely heating them with hot water. For mixing with colours they were only heated to the point at which the granules burst, in which case the suggested test would be quite accurate enough; but there was no reason why the pastes should not be heated to any desired temperature. Among the experiments which he had made, was one in which the paste was poured into long test-tubes before testing. The results were not, however, concordant, owing to air becoming entangled in the starch as it fell into the tube, and unduly facilitating the fall of the spindle.

COMPARATIVE GASOMETRIC ASSAYING, WITH ESPECIAL REFERENCE TO THE VALUATION OF ZINC POWDER, AND THE TESTING OF CARBONATES.

BY J. BARNES.

SOME time ago I devised a method for the valuation of zinc powder,* the value being deduced from the

* Journal of the Chemical Society, xxxix. 463.

by momentary boilings at short intervals until the paper had become pulpy. Each test tube was then submitted to two or three minutes' cooling by immersing it in a beaker of water, and the outside then dried by lightly brushing it over with the edges of several folds of filter paper. After the lapse of about a quarter of an hour, the water in each of the burettes and in the aspirator was brought to the same level, and the readings taken—

Vol. of H from zinc foil = 71.5cc.
 " " " powder = 65.7 "

Considering the zinc foil to be pure Zn, which for commercial purposes may be done, R becomes 1; *w* of course is equal to W, and the calculation is simply—

$$\frac{65.7 \times 100}{71.5} = 91.9 \text{ per cent.}$$

When the tubes are charged with a saturated solution of common salt, acidulated with HCl, the apparatus may be used for the determination of CO₂.

About .25gram. of pure Na₂CO₃ was placed between watch glasses and counterpoised. The sodium carbonate was then brushed off on to a piece of thin paper and folded up. Equilibrium was then restored by calc spar, and the latter likewise folded in thin paper. Both were then placed in the apparatus and treated like the zinc in the previous experiment:—

Vol. from CaCO₃ (standard) = 59.8cc.
 " Na₂CO₃ " = 56.5 "

In this case R = .44, and the following calculation gives the percentage of CO₂ in the Na₂CO₃—

$$\frac{56.5 \times 44}{59.8} = 41.57 \text{ instead of } 41.51 \text{ (the amount theoretically contained.)}$$

The method gives good results, even when the volumes of gas differ considerably more than in the case just given, as for instance:—

.2492gram. calc spar gave 59.6cc.
 .1520 " " " 36.25cc.
 1520 = .6099 3625 = .6082
 2492 = .6099 5960 = .6082

When a large number of samples of the same kind have to be tested, it would obviously be advantageous to have a series of burettes all connected with one reservoir of liquid—one of the burettes serving to collect the gas from the standard, and each of the other burettes to collect the gas from equal weights of the samples. Finally I may draw attention to the fact that in the case of carbonic acid determinations we have in the three carbonates of Ca, Sr, and Ba, a convenient series of standards containing varying percentages of CO₂.

PROFESSOR MILLS IN THE CHAIR.

VISCOSITY DETERMINATIONS.

BY EDMUND J. MILLS, D.S.C., F.R.S.

In the ordinary method of determining viscosity for technical purposes, an oil or other liquid is allowed to run out of a pipette, at a definite temperature, and the number of seconds required for emptying the pipette is observed. A similar experiment is performed with olive oil, used as a standard: the number of seconds required for this being taken as 100, the proportional number of seconds required for the trial oil gives the desired viscosity.

When the ordinary temperature is the temperature of the determination, it is sufficient for technical purposes to work in a room not directly heated, and to carry out the comparison as quickly as possible. For the temperature of 100°, a very simple apparatus, illustrated in the accompanying figure, may be constructed out of materials always at hand in any laboratory. It consists, as will be observed, of a flask—a suitable capacity for which is about 500cc. This is more than half filled with water, and contains in addition, a test tube, in which sufficient lead is inserted to sink it to the bottom of the flask. From the mouth of the flask proceeds a wide tube of adequate length, and in this is placed, centrally, and without contact, the filled pipette, previously closed at the top. After steaming the pipette for a few minutes, its upper orifice is opened, the hot liquid falls gradually into the tube below, and the time for passing certain definite marks is noted. The upper mark is the ordinary graduation mark of the pipette; the lower one should be placed above or at the place where the pipette begins to taper towards its point, there being much retardation of the fall in all lower positions. The method is, in fact, always liable to grave runs if the last few drops which the pipette can hold are taken into account.

A little consideration is sufficient to show that determinations of real viscosity cannot be made in this way. When an oil runs out of a pipette much of it is the subject of mere flow, without shear; and where the viscosity of the oil is low, the relation of the number thus obtained to the actual viscosity must be of a somewhat distant kind. Poiseuille's method is the only one whereby real viscosities can be accurately obtained, but its employment, though sufficiently easy, is undoubtedly not quite so simple as the use of the pipette. The apparatus employed by Poiseuille is perfectly well known in physical laboratories, and consists, as the Section is doubtless aware, of a capillary tube of moderate dimensions (accurately measured) attached to a pipette of capacity well ascertained between two marks. The time of flow from mark to mark is observed as in the usual pipette method. The mathematical formula connecting several of the relations of viscosity was worked out empirically by Poiseuille; it has since been deduced from hydrodynamical considerations by several physicists (cf. Lamb, "A Treatise on the Mathematical Theory of the Motion of Fluids," p. 224; Cambridge, 1879). It has the advantage of being easily read in centimetre-gramme-second units. In this way, each determination of viscosity has a meaning of its own, apart from comparison; or, if a comparison be required, a list of substances can be provided for this purpose, and the same results can be obtained by different investigators, using different apparatus, and operating

in different localities. I have accordingly thought it might be useful to technologists if I were to place on record a few results obtained under fairly definite conditions. The capillary tubes had radii ranging from .0956mm. to .2545mm., a length of 71.73 to 82.16mm., and were worked at pressures under 1000mm. (water). The temperature was kept, by means of a water-jacket, as nearly as possible at 12° C. As regards the liquids examined, the ether was prepared from ethylic alcohol, the water had been recently boiled, and the remaining substances were of a high degree of purity.

If Q be the number of cubic millimetres of liquid traversing in t seconds a capillary having a radius r millimetres and a length l millimetres, under a pressure of p millimetres of water, the viscosity in absolute measure is given by the equation—

$$V = \frac{\pi t p r^4 \times 98.1}{8 Q l}$$

It is assumed that there is no slip.

The results are contained in the following table. Specific gravities at 12° C. are stated, water at 12° being unity.

VISCOSITIES AT 12° C.

Castor "96511	21.721	185410

DISCUSSION.

Mr. STANFORD, after alluding to the difficulties attendant upon viscosity determinations, invited full discussion of the paper.

Mr. PATTISON wanted to know what was the relation between the lubricating power of an oil and its viscosity. The table gave for sperm oil a viscosity of 5876.2 (water=100), and olive oil a viscosity of 9726.8, yet they preferred the former as a lubricant. Castor oil again, with a viscosity of 185,440, or about 20 times as great, had not nearly so high a market value for lubricating purposes as olive oil. Was there any relationship whatever between the two?

Mr. FYFE said that many undoubtedly bought their oils on the strength of viscosity tests exclusively. This was most misleading, for sperm oil at once suggested itself as low in viscosity, and highest in lubricating power. Nobody would accuse melted indiarubber or resin of being lubricants, notwithstanding their high viscosity. So far as the oil trade was concerned, buyers were now finding this out for

themselves. The apparatus exhibited was most interesting. The well-known defects in the apparatus at present in use had induced many minds to devote attention to the subject, and as a result they already had pendulum, air-bell, and more lately Redwood's agate viscosimeters.

Mr. TERVER, as an oil works manager, agreed with the previous speaker that it was a mistake to estimate the practical value of a lubricant by its viscosity. The author had pointed out the importance of preserving a constant temperature during these viscosity determinations. Supposing as a practical test they took one of Napier's little machines, and ran it at a very high speed with best mineral lubricating oil, they would find the oil to be little or no good, but with a burning oil of low viscosity the friction almost entirely disappeared. Again, if they heated the rubbing parts and applied the lubricating oil, its lubricating property was enormously increased, though its viscosity was diminished. Again, the very thickest and most viscous fractions of our mineral oils were perfect lubricants at a low speed, but absolutely worthless at a high one. Thus mere viscosity was no criterion of the value of a lubricant.

Mr. J. S. THOMSON said that they were indebted to the author not merely for devising a machine to test viscosities, but for showing them how to make any number of apparatuses which would give concordant results in the hands of operators, an end by no means attained by the common pipette method. They now had a formula which would enable them to reduce their results to an absolute standard. He had recently seen a process suggested for determining viscosity, by noting how long an air bubble took to rise through a given column of liquid.

Mr. T. L. PATTERSON suggested that the greater viscosity observed in the case of some of the vegetable oils of low lubricating value was due to oxidation of the oil as it passed out of the capillary tube during the determination. These vegetable oils, and especially castor oil, were very easily oxidised, and always "gummed" when applied on journals. Had the author tried any experiments in that direction?

Professor MILLS, in reply, said that, as Mr. Fyfe had pointed out, viscosity was only one factor in determining the value of oils. Durability and liability to chemical change must also be borne in mind. Cohesion and friction altered with the speed of rotation; in fact the coefficient of friction changed three times during a progressive increase in the rate of revolution from a very low rate of speed up to about 2000 revolutions per minute. Frictional alteration was not a means of valuing lubricants; thus for example tallow was far more liable to chemical change at a high temperature, but also much more viscous, than mineral oil. The suggestion that the high viscosity of castor oil was due to oxidation during the determination was entirely out of the question. Castor oil did not "gum" in an apparatus of that kind. But on the other hand, the greater viscosity of castor oil doubtless turned upon the fact that it was one-third more oxygenated than an oleic glyceride of the ordinary type. If they were to theorise about the intimate constitution of castor oil, they might suppose it to be in itself a ready gummed oil, on account of its being more highly oxygenated. Mr. Ellis and himself had been engaged for many years in carrying out a whole series of investigations on viscosities, by ascertaining the laws which regulated the ascent of hollow glass bulbs in various media. But they got far too close a scale of viscosity—i.e., the numbers were far closer together than the "Poiseuille" figures; so that in order to obtain the true viscosities which he had laid before the meeting he had had to revert to the old method of Poiseuille.

ON MAUMENÉ'S TEST FOR OILS.

BY CHAS. J. ELLIS, F.C.S.

MAUMENÉ'S* test for oils, which consists in noting the rise in temperature which occurs when an oil is mixed with strong sulphuric acid, is one of very considerable importance, and yields results of greater quantitative value than might at first be expected. A suitable weight of oil to use is 15grms.; this is weighed in a beaker of about 50cc. capacity; 5cc. of strong sulphuric acid, of 1·84 sp. gr., is then run carefully down the side of the beaker, and forms a layer below the oil. The bulb of a thermometer is then immersed in the mixture and the temperature noted. The acid and oil are then stirred together rapidly, using the thermometer as stirrer, when the temperature rises; after the mixture is complete (usually in from one to two minutes), the maximum temperature is reached, which is also noted, and the rise in the temperature for the oil in question thus obtained. In the case of oils such as olive oil, rape oil, cottonseed oil, etc., results of several experiments coinciding within 1° C. are easily obtained, and when two of such oils are mixed together the percentage of each present in the mixture can be determined—at any rate, to within a small fraction—by noting the rise in temperature which takes place on mixing the oil with sulphuric acid in the above proportions.

The object of this paper is to lay before the Section the notes of some experiments which I have recently carried out with the view of extending the application of this test to such oils as the drying oils, linseed, poppy, nut, etc., and to fish oils, to which it cannot be directly applied without some slight modification. If linseed oil, for example, is mixed with strong sulphuric acid directly, as in the case of olive oil, the action is extremely violent; the liquid froths up, and a large quantity of gas is given off, which of course carries away a great quantity of heat with it, and no standard numbers can be obtained, which would be applicable to the quantitative estimation of such oils when mixed with any of the oils to which the test is directly applicable. Evidently, then, it is necessary to mix with a drying or a fish oil some liquid which will moderate the action of the sulphuric acid upon it. The liquid I used for this purpose was a mineral lubricating oil of 915 sp. gr., and as, on mixing sulphuric acid with such an oil, a certain rise in temperature takes place, it is first necessary to determine the rise due to each gramme of the mineral oil. This I tried to do directly, but with no great success, as the action was so extremely sluggish that the mixture necessarily lost a certain quantity of heat during the experiment, as it required nearly ten minutes' stirring before the maximum temperature was reached. To accelerate the action, I mixed the mineral oil in certain proportions with colza oil, for which the standard number, when not mixed, was accurately determined, and found to be 55·8° C. It might be expected that various mixtures of these two oils would show, as rise of temperature, a mean between the rise shown by each oil separately, depending exactly on the proportions in the mixture; that is to say, supposing a mixture is taken of n grms. mineral oil and $(15-n)$ grms. colza, and that y represents the rise due to each gramme of the mineral oil, and $\frac{55·8}{15}$ the rise due to each gramme of colza, we might expect to get a total rise of $ny + (15-n)\frac{55·8}{15}$ degrees C. This, however, appears not to be quite the case; and the

smaller the quantity of mineral oil in the mixture the greater appears to be the value of y , if we suppose the rise due to each gramme of the vegetable oil to remain constant, whatever the mixture. Probably it is not exactly so, but it is convenient to credit all the discrepancy to the retarding oil, and then a simple formula can be employed which allows of the rise in temperature due to each gramme of the mineral oil being calculated:—

Let y = rise in temperature due to each gramme of mineral oil;

x = the fraction of the mixture consisting of mineral oil;

a and b = constants depending on the conditions of the experiment and the particular mineral oil employed.

Then $y = a + bx$.

I have tabulated below the results of experiments, and it is seen that the experimental value obtained for y , on the above assumption regarding the vegetable oil, agrees, within error of experiment, with the value calculated from this formula. Colza and olive were the two oils which I used, but apparently the same conclusion could be deduced from others, if the maximum temperature attained in the experiment is not allowed to exceed about 60° C., for the numbers which I have worked out for the drying and fish oils have all been calculated from experiments on mixtures containing at least two different proportions of mineral oil, and these agree tolerably closely.

TABLE I.—Mixture = 15grms. (Colza and Mineral Oil.)

x	Rise in temp.	Due to Colza.	y
—	55·8° C.	55·8° C.	—
$\frac{1}{2}$ = 5 grms.	15·0	37·2	1·560° C.
$\frac{1}{3}$ = 7·5 ..	37·75	27·9	1·313
$\frac{2}{3}$ = 10 ..	28·75	18·6	1·015
$\frac{4}{5}$ = 11·25 ..	21·1	13·95	·902

TABLE II.—Mixture = 15grms. (Olive and Mineral Oil.)

x	Rise in temp.	Due to Olive.	y
—	39·6° C.	39·6° C.	—
$\frac{1}{2}$ = 5 grms.	31·0	26·1	1·520° C.
$\frac{1}{3}$ = 7·5 ..	29·7	19·8	1·320
$\frac{2}{3}$ = 10 ..	23·1	13·2	·990
$\frac{4}{5}$ = 11·25 ..	19·75	9·9	·876

The value for a , deduced from the above experiments, is 2·116; and for b , -1·644. Table III. gives, side by side, y , calculated from the formula, and y , taken from the mean value in Tables I. and II. In the fourth column I have placed the total number of degrees C. to be deducted for the mineral oil for each value of x .

TABLE III.

x	y from $y = a + bx$	Mean experimental value of y .	To be deducted from rise for Mineral oil.
$\frac{1}{2}$	1·568	1·540	7·84
$\frac{1}{3}$	1·294	1·316	9·70
$\frac{2}{3}$	1·020	1·003	10·20
$\frac{4}{5}$	·883	·889	9·93

* Paris, *Comptes Rendus*, xxv. 1852, pp. 572–573. *Erdm. Journ. Prakt. Chem.*, lviii. 1853, pp. 26–28. *Journ. de Pharm.*, xxv. 1854, pp. 210–215.

Tables IV. and V. give the results of experiments with several drying and fish oils; Table IV. relates to mixtures containing $\frac{1}{3}$ of the oil in question and $\frac{2}{3}$ of mineral oil; Table V. to mixtures containing $\frac{1}{4}$ of the oil in question and $\frac{3}{4}$ of mineral oil, the total weight of the mixture used being, of course, 15 grms. In the third column I have placed the maximum temperature attained, as, in almost all the experiments, I found that the higher the maximum temperature the higher the value for each gramme of the oil in question, and that when the maximum temperature was much over 60° C. no concordant results could be obtained, which seems to indicate that above that temperature further reactions set in between the sulphuric acid and the oil. It is therefore of importance that the mixture should be made in such proportions that the highest temperature attained may be below 60°—in fact, it is well to keep it even below 50°. This can easily be managed by making a preliminary trial of the quantity of mineral oil to use. All these numbers are the means of several determinations agreeing fairly closely.

TABLE IV.

NAME OF OIL.	Rise in temp. —10° 2° for Mineral oil.	Maximum temp.	Rise due to each gramme of oil in question.
Linseed (raw) . . .	39.1	60°	7.82
" (boiled) ..	33.8	55	6.76
Poppy-seed	22.3	46	4.46
Nut oil	25.6	45	5.12
Scotch cod-liver ..	38.0	56	7.60
" skate-liver..	39.5	58	7.90
" ling-liver ..	30.3	51	6.06
Haddock-liver	38.0	60	7.60

The bromine absorptions (with the exception of the two linseed oils and the nut oil, which were specially determined for this paper) are taken from papers by Dr. Mills, on "The Quantitative Estimation of Fats and Oils," and on "Bromine Absorptions" (this Journ. pp. 366—368, 1884, and pp. 96—98, 1885). Besides the above oils, I made a test of a good average sample of rosin oil. This was determined without admixture of mineral oil, and the rise for each grm. found to be 1.53°.

In order to test the practical value of the above numbers for determining the quantity of two oils in a mixture, I had mixtures made up for me by another, the percentage composition of which I was not told till after returning the results obtained by experiment. Two mixtures of two oils each were given me, the first consisting of cod-liver and ling-liver oils. This I examined by Maumené's test, using a mixture of the oil with twice its weight of mineral oil added, and found it contained 43.3 per cent. cod-liver and 56.7 per cent. ling-liver, the actual mixture being 41.7 per cent. cod-liver, and 58.3 per cent. ling-liver. The other mixture was colza and raw linseed. On testing this mixture with twice its weight of mineral oil added, I found 31 per cent. linseed and 69 per cent. colza, and with three times its weight of mineral oil added, 30.9 linseed and 69.1 colza, the actual mixture being 29.9 per cent. linseed and 70.1 per cent. colza. It is hardly necessary to mention, in conclusion, that y , a , and b in the formula ($y = a + b.r$) must be specially determined by experiment for any particular mineral oil which is to be used as retarding agent, and that if the numbers given are used as standards, the conditions of the experiment must be strictly adhered to.

DISCUSSION.

MR. TERVET asked if allowance had been made for the relative specific heats of the oils experimented upon? Mineral oil had a very low specific heat as compared with certain animal and vegetable oils;

TABLE V.

NAME OF OIL.	Rise in Temperature—9° 95 for Mineral Oil.	Maximum Temperature.	Rise due to each Grm. of Oil in question.	Bromine Absorption.
Linseed Raw	28.57	48°	7.62	81.25%
Linseed Boiled	24.87	46°	6.63	81.50
Poppy-seed	17.32	37°	4.62	56.51
Nut Oil.....	17.99	35°	4.80	72.74
Cod-liver.....	27.82	48°	7.42	81.61
Skate-liver.....	29.77	48°	7.91	109.20
Ling-liver	22.07	41°	5.88	82.44
Haddock-liver	27.57	49°	7.35	109.84

It will be noticed that in most cases the numbers in Table V. are slightly lower than in Table IV., the maximum temperature being also lower. Poppy-seed oil and nut oil were most affected by a change in maximum temperature, and it was extremely difficult to obtain concordant results with those oils at different temperatures. I tried mixtures of half mineral and half of each of these oils, and the numbers were considerably higher than the above. Cod-liver, skate-liver, and haddock-liver oils show approximately the same numbers; but ling-liver distinctly lower. At the commencement of the mixing of the acid with the fish oils, a purple colour is noticed, which soon changes to brown. This purple colour is particularly intense in the case of ling-liver.

and if one of these latter were mixed with various proportions of mineral oil, the amount of heat generated must vary in proportion to the amount of mineral oil present. For instance, if in one experiment colza and A proportion of mineral oil were taken, then the resulting temperature ought to be different from that obtained when colza and B proportion of mineral oil were mixed together.

MR. STANFORD asked what was the range of temperatures in these mixtures, at least some of the more important ones?

MR. McARTHUR asked what action took place between sulphuric acid and these vegetable oils? Did the amount of heat generated depend on the amount of oxygen in the oil; and why was colza oil used as

a medium? Would not water do to dilute the sulphuric acid with?

Mr. J. S. THOMSON pointed out a feature in the analysis of fatty oils which the author had not touched upon. No doubt his modification of Maumené's test enabled him to deal with mixtures of two known oils. But suppose they were given a sample of rape or seal oil, stated generally to be adulterated, the question would at once be what the adulterant was, and until that was settled the test would be useless. He knew of no method which would enable them to determine the relative proportions of two oils, the very nature of which was unknown.

The CHAIRMAN said that the author's paper certainly put Maumené's test for oils on a more satisfactory footing, and his modification enabled them to class oils which hitherto the test had failed to deal with. By adopting this expedient of diluting the oil, he had succeeded in obtaining temperatures by which he could ascertain within about 2 per cent. the composition or admixture of two oils not mixed by himself. This was a most important result, for he had thus given precision to a test which had heretofore materially lacked it.

Mr. ELLIS said: In reply to Mr. Tervet's remarks, I do not see that different oils having different specific heats has much to do with the matter in hand. It is a simple fact that a given rise in temperature results when any particular oil and strong sulphuric acid are mixed in given proportions. Of course the specific heat of the oil in question is one factor in the cause of the particular rise for that oil; but the effect is all that the test is concerned with. I have specially stated, at the end of the paper, that if the numbers given are used as standards, the exact conditions of the experiment must be adhered to. It will be seen from the tables, that in the case of such oils as this paper deals with, the rise in temperature per grm. is less as the proportion of retarding oil in the mixture is greater. Mr. Stanford asks me to give one or two numbers showing the range of temperature in the experiments. The maximum temperature in any experiment was 69° C., the initial temperature being somewhere about 10° in all the cases; the greatest range of temperature was therefore about 59° , and the least was about 27° . It is perfectly easy to get two experiments with a given mixture coinciding within from a half to one degree C. To answer the first of Mr. McArthur's questions would be rather a lengthy matter. As to the second, diluting the acid would hardly be a suitable method of procedure, for the action of dilute sulphuric acid on oils is materially different from that of strong, and in most, if not in all cases, the use of dilute acid would cause too trifling a rise in temperature to serve as a test of any degree of accuracy. I agree with the gentleman who spoke last, that the qualitative tests for oils, as at present known, are as a rule extremely poor; but from evidence gained by applying several quantitative tests to any mixture containing not more than two, or at most three oils, which is generally the case in practice, a very fair idea of what the various oils in the mixture are, can generally be obtained. However, this paper does not profess to deal with the qualitative testing of oils, but is merely an extension of one of the more useful quantitative tests.

ON THE ESTIMATION OF ALUMINA AND OXIDE OF IRON IN MINERAL PHOSPHATES AND MANURES.

BY ROBERT T. THOMSON.

THIS process is in a somewhat unsatisfactory condition, and this is chiefly due to the ignorance which

prevails with regard to the composition of the phosphates of aluminium and iron, which are precipitated in the ordinary method of determination. The following investigation was made with the view of ascertaining the best process of determining these compounds in the phosphates of commerce. It will be desirable to consider first the methods of separating the phosphates of aluminium and iron from acid solutions containing these bodies, in conjunction with phosphate of lime.

Ammonium Acetate Method.—This is the chief or only method extensively in use for the separation of alumina and oxide of iron from phosphates of lime, etc. Dr. James Bell ("Chemistry of Foods," Part II.) has objected to the operation being conducted in the cold, on the plea of incomplete precipitation. As the result of many experiments I have never had a single case of the precipitation being defective in the cold, except where there was a great deal less phosphoric acid present than was required to form normal aluminium phosphate. This being the case it would seem advisable to adhere to precipitation in the cold, or at most only warm solution, seeing that phosphate of lime is easily enough carried down, without increasing this facility by resorting to an aimless boiling. In the experiments which I shall quote this method was employed in the following manner: To the acid solution to be tested, which varied from 100 to 200 cc. in bulk, ammonia was added, till a slight cloudiness was produced, and then 50 cc. of ammonium acetate solution, which had been previously mixed with 5 cc. of ordinary acetic acid. The ammonium acetate was prepared by neutralising a quantity of the acetic acid referred to (containing about 40 per cent. $C_2H_3O_2$), with ammonia, of sp. gr. 94. The mode of washing the precipitate will be described further on.

Neutralisation Method.—I have named this the neutralisation method, because it consists in simply adding to the acid solution of the mixed phosphates, ammonia, soda or potash, until neutral to lakmoid paper. In a paper published about two years ago, I incidentally called attention to the fact that when an acid solution containing the phosphates of aluminium, iron, and calcium was neutralised with caustic soda, using methyl orange as indicator, the two first-named compounds were precipitated. When these are present in considerable quantity, it is almost impossible to get a good end-reaction with methyl orange, but I have found that the neutralisation can be effected with great accuracy when blue lakmoid paper is employed. The best way to proceed is to neutralise the most of the free acid with dilute ammonia (about sp. gr. 97), then drop half normal ammonia from a burette till the blue colour of the paper is unchanged, or shows only a faint alteration towards purple, when immersed in the mixture for a minute or two. At this point the phosphates of aluminium and iron are entirely precipitated, while the most acid phosphates of calcium ($CaH_2(PO_4)_2$), magnesium, ammonium ($NH_4H_2PO_4$), sodium and potassium (if all are present), remain in solution.

Composition of the Aluminium Phosphate Precipitate.—Having now described the methods of precipitation, the next step is obviously to determine the composition of the phosphates thus obtained, and we will first consider that of the aluminium phosphate. Experiments were made by dissolving varying quantities of ordinary phosphate of sodium of known strength, in water, adding a little hydrochloric acid, and 1 grm. of pure ammonia alum, in which the alumina had been determined by precipitation with ammonia. The solutions thus obtained were now precipitated in the cold by the two methods described above, filtered, and washed first with cold, and then thoroughly with hot water. After washing several

times with water, the filtration became tedious, and the precipitate partially lost its gelatinous form. The highest weight of precipitate obtained, even with ten times more phosphoric acid than was required to form normal aluminium phosphate, was 2491, instead of 2700gm., had pure $Al_2P_2O_5$ been weighed. Similar results were brought out when the precipitate was washed with dilute ammonium acetate, although the presence of the ammonium salt enabled the precipitate to retain its gelatinous condition, and made the filtration much more speedy. The following were the results:—

Ammonia alum used 1grm.
= Al_2O_3 2135 „
= $Al_2P_2O_5$ 2700 „

Equivalents of P_2O_5 added.	Weight of Al Phosphate precipitate.	Method of Precipitation.
1	2460gm.	ammonium acetate.
5	2491 „	„ „
1	2465 „	neutralisation.
2	2482 „	„
5	2490 „	„

Considering that these results are tolerably close to each other, I at first drew the conclusion that a basic phosphate of aluminium, of fairly constant composition, was precipitated, even when a large excess of phosphoric acid is added. But this idea had to be rejected when I afterwards found that pure water had a dissociating action on precipitated aluminium phosphate, and that the washings came away slightly but distinctly acid, long after the excess of phosphoric acid employed could reasonably be expected to be washed away. An experiment with 1grm. of alum was made to prove this. The precipitation was effected by the neutralisation method, and only about four-fifths of the phosphate of sodium required to form normal phosphate with the alumina present was added. The filtrate (about 100cc) contained about 6milligrams. of P_2O_5 , and the precipitate was washed several times with hot water to remove any traces of acid phosphate of sodium or ammonium that might remain. The washing was then continued with hot water, until half a litre of filtrate was obtained, and the phosphoric acid determined. The results showed 21milligrams. of P_2O_5 , but alumina could not be detected. The composition of the precipitate was basic to start with, and had it been purely normal, the action of the water would probably have been greater.

The next series of tests was made by the two methods, but the washing was effected with a cold, then a hot one per cent. solution of ammonium nitrate, containing an amount of di-acid ammonium phosphate ($NH_4H_2PO_4$) equal to 05gm. of P_2O_5 per litre, then giving a final single wash with pure water, which would practically remove the phosphoric acid in solution, and not affect the composition to an appreciable extent. The phosphoric acid was estimated in a portion of the filtrate obtained by washing the precipitate, and the proportion found agreed with that really present in the original solution. It was thus apparent that the latter was without action on the aluminium phosphate precipitate. The following are the results:—

Equivalents of P_2O_5 added.	Weight of Al Phosphate precipitate.	Method of Precipitation.
1.5	2606	neutralisation.
2	2695	„
5	2704	„
2	2702	ammonium acetate.

These results show that if at least two equivalents of P_2O_5 and one of Al_2O_3 are present together, normal aluminium phosphate ($Al_2P_2O_5$) is precipi-

tated, but can only be retained in that condition by the mode of washing suggested. The compound formed in presence of two equivalents of phosphoric acid was analysed, and gave the following figures:—

	$Al_2P_2O_5$ Precipitate.	Theoretical Composition of $Al_2P_2O_5$.
Al_2O_3	43.65	42.04
P_2O_5	56.70	57.96
	100.35	100

The phosphoric acid was determined by the combination of the molybdate and magnesia methods, and the alumina was estimated in the molybdate filtrate by precipitation with a slight excess of ammonia.

I may also notice at this stage another method of precipitating aluminium phosphate. This is also a neutralisation method, but is the reverse of that already described, and consists in adding hydrochloric acid to a caustic soda solution of alumina and phosphate of sodium, until neutral to lakmoid paper. An experiment with one equivalent of P_2O_5 to one of Al_2O_3 gave 2380gm., and with two equivalents 2505gm. of aluminium phosphate, instead of 2700 gm. It would thus appear that even with two equivalents of phosphoric acid a basic compound is formed, and it would no doubt be unsafe to use this method of neutralising, even if more phosphoric acid would give rise to a normal compound.

Composition of the Iron Phosphate Precipitate.—All the remarks made with regard to the aluminium phosphate apply to the analogous iron compound. The precipitate is also decomposed when subjected to hot-water washing, and requires the same washing with ammonium nitrate solution, containing a minute quantity of di-acid ammonium phosphate, to enable it to retain the normal condition. The following are the results of experiments made with 1grm. of pure iron alum ($Fe_2(NH_4)_24SO_4 + 24H_2O$), using different proportions of sodium phosphate, and precipitating by both methods:—

Iron alum used 1grm.
= Fe_2O_3 1660 „
= $Fe_2P_2O_5$ 3133 „

Equivalents of P_2O_5 added.	Weight of Fe_2 Phosphate precipitate.	Method of Precipitation.	
1	2756gm.	neutralisation.	} washed with water.
5	2980 „	„	
1	2770 „	ammonium acetate.	
1	2985 „	neutralisation.	
1.5	3125 „	„	
5	3134 „	„	
1.5	3130 „	ammonium acetate.	
5	3137 „	„	

The precipitates of the last five experiments were washed with the ammonium nitrate and phosphate mixture. It is obvious that those obtained with 1.5 (and upwards) equivalents of phosphoric acid are purely normal phosphate of iron ($Fe_2P_2O_5$). One of them was analysed, and gave:—

	$Fe_2P_2O_5$ Precipitate.	Theoretical Composition of $Fe_2P_2O_5$.
Fe_2O_3	53.05	52.98
P_2O_5	46.82	47.02
	99.87	100

Effect of Metallic Salts.—Two experiments were finally made by both precipitation methods, in order to observe whether the presence of metallic salts, other than those of ammonium, sodium and potassium, had any effect on the accuracy of the results. The determinations were made in both cases with a mixture of 25gm. ammonia alum, 25 iron alum, 5

manganese sulphate, 5 zinc sulphate, 5 calcium chloride, and 5 of magnesium sulphate. The precipitates should weigh, if nothing else were carried down, 1458 grm. By the neutralisation method, 1523 grm. was obtained, and this is not so very far out, as it contained a little manganese, which could be removed by dissolving and reprecipitating. By the acetate of ammonia process the precipitate weighed 2726 grm., or nearly double the correct weight, and it contained both manganese and zinc. Neither of the precipitates contained appreciable quantities of lime or magnesia. It is evident that the ammonium acetate process would be useless in presence of manganese or zinc, but that the neutralisation would effectively separate these metals. I had not time to make confirmatory quantitative experiments on this part of the subject; but qualitative tests showed that on mixing sulphate of manganese or zinc with phosphoric acid, a precipitate was produced on addition of ammonium acetate; but no effect was observed on neutralising with ammonia, when lakmoid paper was employed as indicator, the addition of alkali being stopped when the paper showed a slight change to purple.

Summary of Determination of Alumina and Oxide of Iron in Commercial Phosphates.—Two or three grms. may be taken, dissolved in hydrochloric acid, evaporated to dryness, the residue dissolved again in hydrochloric acid, diluted, and filtered. The phosphates of aluminium and iron are then precipitated, either by ammonium acetate or neutralisation, as described at the outset of the paper. The large excess of acetic acid used in the former case may be objected to, but only by its influence can all the lime be removed. It has no effect on the precipitates. The precipitate is then collected on a filter, and washed several times with cold one per cent. solution of ammonium nitrate containing di-acid ammonium phosphate ($\text{NH}_4\text{H}_2\text{PO}_4$), equivalent to 0.5 grm. P_2O_5 per litre. It must then be thoroughly washed with the same solution (hot), and finally once with pure water, then dried, ignited, and weighed. It may then be dissolved in hydrochloric acid, reduced with protochloride of tin, and the iron determined by standard potassium bichromate. The result is calculated to $\text{Fe}_2\text{P}_2\text{O}_8$, which is subtracted from the weight of the precipitate, and the remaining $\text{Al}_2\text{P}_2\text{O}_8$ calculated to alumina. The following results were obtained by mixing about 3 grms. of $\text{Ca}_3\text{P}_2\text{O}_8$, with varying quantities of ammonia alum and iron alum, and determining the alumina and oxide of iron as described:—

Grm. of Al_2O_3 used.	Grm. of Al_2O_3 found.	Grm. of Fe_2O_3 used.	Grm. of Fe_2O_3 found.
*0341	*0352	0332	0339
*0341	0348	0498	0500
*0341	*0346	0498	0499
*0568	*0580	0830	0835
*0568	0578	0830	0835

Those marked with an asterisk were done by the neutralisation method.

If a high result is apprehended from the precipitation of phosphate of lime, the precipitate may be dissolved in hydrochloric acid, excess of caustic soda added, boiled, and filtered. The iron can then be determined by a volumetric process in the insoluble, and the alumina determined in the filtrate, after acidifying with hydrochloric acid, by either of the methods described above. It would be well, however, to add some phosphoric acid or phosphate of ammonium, to ensure the presence of an excess of the former sufficient to produce normal aluminium phosphate.

Dr. Clark has mentioned to me that in certain

mineral phosphates containing fluoride of calcium, he could not get the precipitated phosphates free from lime, even after redissolving and reprecipitating. This he thinks is possibly due to the precipitation of fluoride of calcium, which might not be decomposed by evaporation with hydrochloric acid. I have found that a mixture of chloride of calcium and hydrofluoric acid does give a gelatinous precipitate with ammonium acetate. Of course, this interference of fluorides can be obviated by first heating the weighed portion of the sample with strong sulphuric acid till these compounds are decomposed, and all the hydrofluoric acid is expelled. The residue may then be treated with hydrochloric acid, and the determination proceeded with.

Addendum.—Since writing the above paper, the author has made experiments with reference to washing the phosphates of aluminium and iron with cold water, and finds that the latter has also a dissociating action on these compounds. The experiments are also being carried out with mineral phosphate of alumina, etc.

DISCUSSION.

Mr. HENDERSON understood the author to state that precipitated phosphates of aluminium and iron were decomposed when washed with boiling water, phosphoric acid being carried away in solution, and basic phosphate left behind. Did this decomposition go on indefinitely, or did it cease when a stable basic phosphate of definite composition was reached?

The CHAIRMAN asked how far this dissociation of phosphates was likely to occur in soils? Did it increase materially as the water grew hotter; for if it took place in the cold it would be of considerable importance to agriculture, in connection with the manurial values of iron and aluminium phosphates, and their exhaustion.

Mr. THOMSON, in reply, said that these were points to which he would direct future experiments.

THE ESTIMATION OF SULPHUR IN COAL AND COKE.

BY ALEXANDER J. ATKINSON.

THE estimation of sulphur, whether in coal or coke, or in sulphur compounds, resolves itself in most cases into the conversion by a process of oxidation of the sulphur into a soluble sulphate, from the solution of which it is precipitated by the addition of barium chloride. Hence in the mode of precipitation little opportunity is offered for modifications, but in the modes of oxidation many variations have been suggested. The methods of oxidation hitherto adopted may be grouped into three classes according to the nature of the oxidising agent employed—viz.: 1st.

Oxidation by means of *solid* oxidising agents—*e.g.*, potassium nitrate or potassium chlorate; this mode of oxidation is that commonly known as the *Deflagration Method*, and is the principle hitherto most commonly adopted in the estimation of sulphur in coal and coke; 2nd. Oxidation by means of *liquid* reagents—*e.g.*, fuming nitrate acid or *aqua regia*; this is the principle of a method advocated by Dr. Lunge, and now extensively adopted for the determination of sulphur in pyrites; 3rd. Oxidation by *gaseous* reagents, notably oxygen as contained in atmospheric air. This last-named mode of oxidation is finding more and more favour with chemists who have to make many determinations of sulphur in coal or coke owing to the readiness with which the various steps are carried out.

As methods falling under the two first of the above-named headings have already been fully described by previous writers, and as they have little in common with the modified method presently to be submitted, it is needless to dwell upon them here further than to remark that, although in careful hands exceedingly accurate results may be obtained by their adoption, yet all these methods require unremitting attention during the oxidation stage, and are otherwise more dependent upon minute precautions than methods based upon the oxidation by atmospheric oxygen.

As far as the writer has been able to trace the history of this subject, it appears that the first suggestion to employ a gaseous oxidising agent was made in the year 1874 by Herr Eschka,* who described a method by which to oxidise the sulphur in the coal—by ignition in a platinum crucible over a spirit-burner—of a mixture of the coal with calcined magnesia and sodium carbonate. Eschka appears to have considered that the oxidation to the state of sulphuric acid was incomplete, for he recommends the subsequent addition of ammonium nitrate and further ignition in order to complete the oxidation.

In the same year as Eschka's method appeared, Mr. W. F. K. Stock† published his method based upon the use of calcium hydrate as the absorbent of the sulphuric acid formed. It is here proposed that the weighed portion of coal be mixed with an equal weight of slaked lime, moistened with water so as to form a thin paste, the moisture dried on a hot plate, broken into a coarse powder by grinding in the crucible, and then heated in a muffle to bright redness. After ignition, the capsule is allowed to cool, ammonium nitrate added, the mixture again dried and ignited. After cooling, the mass is dissolved in dilute hydrochloric acid, filtered, and in the filtrate the sulphur is precipitated as barium sulphate.

A few years later, in 1879, a Japanese, Mr. T. Nakamura,‡ contributed to the Chemical Society a method of oxidation by means of atmospheric oxygen, in which the use of calcium hydrate as an absorbent of the sulphuric acid formed is replaced by that of sodium carbonate, while the combustion of the carbon is effected at a dull red-heat over a spirit lamp. This is, in principle, the method which has recommended itself best to the writer, who now proposes to deal with the few modifications which he has found well to introduce. The difficulty with which the heat from a spirit lamp can be evenly distributed over the whole of the test suggested to the writer that the combustion could be more easily conducted in a muffle through which a gentle current of air is made to pass. Several experiments were made with such satisfactory results that the deflagration

method, adopted until then, was abandoned in favour of the method which now, after about six years' working, I propose to introduce to the notice of members of this Society.

As it is necessary that the coal or coke to be examined should be in a state of extreme fineness, it should, after drying at 100° C., first be ground in an iron mortar until it will pass through a sieve of 120 meshes to the linear inch, then thoroughly well mixed, and from it a portion taken somewhat in excess of that required for a duplicate test; this portion is then to be ground in a Wedgwood or iron mortar until no feeling of grittiness is perceptible, then dried in a good desiccator, and from it two test portions of respectively 1.0 grm. and 1.2 grm. weighed out. Each of these test-portion is then intimately mixed, by grinding in a mortar with a weighed quantity (5 grms. and 6 grms., respectively) of redried pure anhydrous sodium carbonate. This mixture is next introduced into a flat platinum dish, spread evenly over the bottom of the dish, and placed on a rectangular rest made of clay-pipe stems inside a muffle, which, though hot, is still black. Before introducing the test into the muffle, the operator should so arrange the fire that the heat will rise gradually in about half-an-hour from blackness to clear cherry-redness—it should not be allowed to rise so high as to sinter or fuse the sodium carbonate—and at a clear cherry-red heat the test is allowed to remain for ten or fifteen minutes; at the end of this time all the carbon, and with it all the sulphur, will be found to have been burnt, the passage of a constant current of air through the muffle being insured by a slit at the back of the muffle. It is unnecessary—indeed, undesirable—to stir the test during ignition, and with a muffle well under control the operation requires no attention during the forty-five minutes that the test is in the muffle. At the end of this time it will be found that the sulphur has been entirely oxidised and absorbed by the sodium carbonate, a portion of the carbonic acid giving place to sulphuric acid, no addition of ammonium nitrate being necessary for complete oxidation. The ignited sodium carbonate, mixed with the resulting sodium sulphate and coal-ash, is now brought into a small beaker, the last traces being washed into the beaker from the platinum dish, and water added, the volume of liquid being 120 to 150 cc. Solution is aided by heating and agitation, and when all soluble matter is dissolved, the beaker is allowed to stand on a warm part of the hot plate until the insoluble matter has settled. The clear solution is now passed through a small Swedish filter into a beaker with high sides; the insoluble matter is washed twice by decantation with hot water, a few drops of a solution of pure sodium chloride being added at each washing in order to avert the tendency of the finely divided ash to pass through the filter. After washing by decantation, the insoluble matter is rinsed on to the filter, and carefully washed with water and sodium chloride three or four times, until a small portion tested with barium chloride gives no precipitate. The filtrate containing all the sulphuric acid is acidified by the addition of 10 to 15 cc. of pure hydrochloric acid, carefully added with the aid of a pipette, and the whole boiled in order to expel free carbonic acid. To the boiling solution a hot solution of pure barium chloride is added, and under these conditions the sulphuric acid is precipitated as barium sulphate in a form in which it rapidly settles. After standing for an hour or an hour-and-a-half, the barium sulphate will have completely settled, and the clear liquid can be poured through a Swedish filter. During the operation of washing this precipitate, the use of a

* Oesterreichische Zeitschrift, xxii. p. 111, and Chem. Central-Blatt, 3. Folge 5, p. 301.

† Chemical News, vol. xxx. p. 211 (1871, Nov. 6).

‡ Journal Chemical Society (1879), vol. xxx. p. 785.

small quantity of a solution of ammonium chloride is to be recommended, as this precaution prevents the precipitate passing through the filter, as will otherwise sometimes happen. When washed free from sodium salts the precipitate of barium sulphate may be dried and ignited in the customary manner.

By following this mode of procedure the author has been able during several years to obtain results which, in point of concordance, leave nothing to be desired; and, as these results agree closely with those obtained by the delagration method when carefully conducted, it is probable that where a muffle is available, the greater simplicity of this method will favour its exclusive adoption. There are, however, in the choice of reagents a few precautions which it may be advisable to point out. Experience seems to show that it is perfectly impossible to purchase sodium carbonate absolutely free from sulphate. The sample most nearly approaching this state of purity that we have been able to obtain, is the granulated salt sold by Messrs. Hopkin & Williams. 10 grammes of this salt dissolved in water, acidified with pure hydrochloric acid, boiled and treated with barium chloride gave at first no precipitate, but after standing overnight, a precipitate of barium sulphate had deposited, and this, when collected, was found to weigh 5.2 mg. It is for this reason that weighed quantities of the sodium carbonate are always used, so that the barium sulphate derived from this source may be deducted from the whole weight obtained. It is necessary that the granulated sodium carbonate be finely ground and redried, for unless all hygroscopic moisture is removed a spitting from the open dish takes place, giving rise, of course, to a loss of the test. We experience no difficulty in obtaining hydrochloric acid perfectly free from sulphuric acid, although, until confidence in the purity of the purchased acid is established, an examination ought always to precede the use. Owing to the extreme fineness of the state of division of the coal used, the residual ash is also extremely finely divided, and consequently has a great tendency to pass through even the closest Swedish filter paper, particularly after the greater part of the sodium salts has been removed by washing. In practice, therefore, it became necessary to adopt some means of counteracting this tendency; the use of ammonium chloride in washing barium sulphate precipitates suggested its use here also; this salt prevented the passage of the residue through the filter, but was objectionable on account of ammonia gas being liberated through the decomposition of the salt; a solution of sodium chloride next suggested itself as a probable remedy, a small addition to the large quantity of sodium salts being of little consequence, and the addition of this salt was found to completely prevent the passage of the residue through the filter. Sodium chloride is, however, very difficult to purchase perfectly free from sulphate, and consequently it was found to be advisable to prepare the pure salt in the laboratory, by passing hydrochloric acid gas into a strong solution of table salt. The sodium chloride thus precipitated was then filtered, well washed and dried, and when examined was found to be free from sulphate. It would, of course, be possible to determine the amount of sulphuric acid in the purchased salt, and, by using weighed quantities, to make the necessary correction; but, in the writer's opinion, it is undesirable that the calculations should be complicated by too many such corrections, especially when this can be avoided by so simple a preparation as that of pure sodium chloride.

The advantages, which the method just described presents over that described by Eschka are, that one reagent suffices in the place of three used by that chemist, thus diminishing the risk of deriving sul-

phuric acid from the reagents, that a large amount of insoluble matter—*e.g.*, magnesia, is avoided, and that the solution from which the sulphuric acid is to be precipitated is kept free from nitrates. Over Stock's method it has the advantage that the sulphate formed is readily soluble in water, and, by thus avoiding the necessity of dissolving in hydrochloric acid, the presence of iron and calcium salts in the solution is avoided; it being well known that ferric chloride, when present, together with hydrochloric acid, prevents the complete precipitation of the barium sulphate. As the method described in this paper professes to be merely a modification of Mr. Nakamura's method, by which a more complete combustion of the coal can be ensured, it cannot, from a chemical point of view, be said to have any advantages, but was necessitated by the difficulty found when using a spirit lamp, in completely burning the coal on the surface of the test, without, at the same time, fusing a portion of the sodium carbonate. A coal-gas burner cannot well be used, as the sulphuric acid, formed by the combustion of sulphur compounds in the gas, is, in part, absorbed by the sodium carbonate, and reckoned in the results.

As examples of the concordance of duplicate results, the following taken from our laboratory-book may be quoted:—No. 1, 1.30 and 1.29 per cent. sulphur; No. 2, 0.997 and 0.995 per cent.; No. 3, 1.68 and 1.72 per cent.; No. 4, 0.61 and 0.61 per cent.; No. 5, 0.762 and 0.760 per cent.; No. 6, 0.861 and 0.860 per cent.; No. 7, 0.872 and 0.855 per cent. These figures will suffice to show that concordant results may be obtained by this method; in fact, experience shows that a difference, exceeding 0.05 per cent., should never be met with; they do not, however, afford members an opportunity of instituting a comparison between the results obtained by this method and those given by other methods, and the writer regrets that he is unable to submit figures showing the comparative accuracy of the several methods in use. The comparative tests were made without any intention of the results being published, and the figures, if preserved, are in the laboratory-books of a company whose service the writer left some years ago. Not having had an opportunity of repeating the comparison, I must content myself with mentioning the case of a sample of coke sent me by a friend. By adopting the above method I found the coke to contain 1.14 per cent. of sulphur; and when I next saw my friend I learnt that his determination by the delagration method was precisely the same, 1.14 per cent.

This concludes what I have to say regarding the estimation of sulphur in coal and coke, but if members will allow me, I should like to indicate a direction in which this method may perhaps be extended. Having obtained such satisfactory results when practising upon coal, I ventured to hope that the sulphur contained in pyrites might also be determined by this method, and I have made many experiments with the object of proving the applicability of the method to this kind of analysis, but I regret to say that the results have been far from satisfactory. By finely grinding the pyrites, and mixing with about twenty times its weight of sodium carbonate, I could not obtain results giving more than 96 per cent. of the sulphur contained in the pyrites, as found by the method advocated by Dr. Lunge. By using a larger quantity of sodium carbonate it was thought that a more complete absorption of the sulphuric acid could be effected, but experiments proved the contrary. In order to find whether a portion of the sulphur had been only partially oxidised, the test, after ignition, was treated with bromine, but without obtaining any higher results. The residual ferric oxide was also examined,

but it was found that all the sulphur had been removed during the ignition in the muffle.

Hitherto the writer has been baffled in his attempts to work out the estimation of sulphur in pyrites upon these lines, and is induced to mention his experience in the hope that some other person may more completely grasp the details, and give chemists the benefit of his results. If by some simple device the complete absorption of the sulphuric acid could be secured, the amount of this sulphuric acid might be determined by finding the quantity of standard sulphuric acid required to neutralise the excess of sodium carbonate, and deducting that amount from the quantity which would be required to neutralise the whole of the sodium carbonate weighed out. In this way a ready volumetric method of estimating sulphur in pyrites could be found, which should be accurate enough for technical purposes, and which could be completed within two-and-a-half hours from the time of receiving the crushed sample.

Obituary.

H. SUGDEN EVANS.

HENRY SUGDEN EVANS, born May 19th, 1830, was the youngest son of John Evans, founder of the firms of Evans, Lescher & Webb, of London, and Evans, Sons & Co., of Liverpool, wholesale and export druggists. Educated at the Merchant Tailors' School, and under Dr. Whitehead, of Ramsgate, he was early apprenticed to his father's business in Bartholomew Close. In 1847 he entered as a student at the Pharmaceutical Society, and passed all the examinations, which were at that time voluntary. In 1849 he was elected a Fellow of the Chemical Society. He assisted in the formation of the "Liverpool Chemists' Association," of which he was twice president (1857—1858); and he was also identified with the formation of the "Liverpool Natural History and Microscopical Society." In 1860 he was elected a member of the Council of the Pharmaceutical Society, becoming president in 1869. He represented the Pharmaceutical Society at the International Congress in Vienna, in 1868, and in 1873 served as a juror on Food at the International Exhibition in that city. In 1870 he was awarded the diplomas of the Pharmaceutical Societies of Vienna and St. Petersburg, and was elected a vice-president of the Royal Microscopical Society. He proceeded, in 1879, to Canada, to conduct a branch of his business at Montreal, and in 1884 he retired from mercantile affairs, and accepted the appointment of Chief Analyst to the Dominion. He also established a private practice as a consulting analyst at Ottawa.

In February last he went on Government business to Boston and New York, and it was at the latter place that he was seized with an attack of pneumonia, which proved fatal on the 23rd. His kindness of disposition endeared him to all who knew him, and his loss is deplored by a large circle of friends. His death is also an unquestionable loss to the Dominion Government.

THE RIVERS PURIFICATION BILL.*

From the Manchester Guardian, March 18, 1886.

SIR E. BIRKBECK moved the second reading of this bill on Tuesday night, 16th March.

Sir H. Roscoe, in moving that the bill be read that day six months, said that he did this in no unfriendly spirit to river purification. The importance of the subject of river pollution and its amelioration was one with which hon. members were well aware, and at that late hour he would not trouble the House by any historical survey. He opposed this bill because he was desirous of having a practicable workable scheme in place of this, which he characterised as quite the reverse, being complicated, impracticable, and dangerous, as imperilling the very existence of many of our most important industries, and that at a period of unexampled depression. He desired to point out to the House that whilst the Act of 1876 discriminated between the pollution caused by sewage and that produced by manufactures and mines, no such distinction is drawn in this bill. Such a distinction was, however, absolutely necessary, for whilst sewage impurity had everywhere approximately the same composition, and was therefore capable of treatment by similar methods of purification, manufacturing pollution was of the most varied character, as was seen in the case of breweries, paper works, alkali works, dyeworks, etc. So that not only were the methods which should be employed for purification different, but the standards according to which the purity is to be judged must also be different. In the present bill every kind of pollution was to be judged by one set of standards, and hence these could not but prove inefficacious, being in some cases either so strict as to place a hindrance on industry, or so lax as to be practically worthless. If any progress was to be made with legislation on this important question, the subject must be attacked piecemeal, and this bill was far too sweeping in its provisions. Science was now in a position to deal satisfactorily with sewage. At a certain cost it could be so treated that the effluent was made inoffensive, and therefore there could be no objection to legislation on this subject. But as regarded manufacturing pollution, the same could not be said, and the only method was to apply the best practicable means which was found in the Act of 1876, but was not referred to in the bill now before the House. Then, again, not only were all trades treated alike as regards pollution, but all rivers were placed under the same set of standards, the only difference allowed being between those used for drinking purposes and those not used for drinking. This was an altogether impracticable plan; it was absolutely necessary to consider each river on its merits, and to treat the subject geographically, for the circumstances of each river, or even of each part of a river, were different, and required different treatment. Hence, he thought that this great and important subject was one which could not be properly treated in a private bill, but should be considered by Government. On the part of the manufacturers interested in this question he desired to say that they were in no sense hostile to measures of river purification, provided these measures were framed with due regard to the necessities of industry and carried out by responsible and competent authorities. In the case of the Alkali Acts, with which he (Sir Henry) had had to do, both the public and the alkali manufacturers had greatly benefited, and there was no reason why this should not also be the case with water as well as with air pollution. Referring to a few clauses which he

* See this Journal, iii. 581; iv. 2, 94, 98, 157, 165.

thought most dangerous, he pointed out, in the first place, that in Clause 2 a single sample of water collected at one moment from a river might be taken to prove an offence against the Act. This was, however, obviously unfair, as an average of the twenty-four hours was absolutely necessary in order to obtain any knowledge of the condition of the river. Again, in Clause 3, the judge was made responsible for a given method of purification, whereas he ought only to be responsible for results, and should have nothing to do with how that result was arrived at. Clause 6, again, opened the door to malicious or factious legislation, as it actually permitted any individual, without incurring any expense, to bring actions through the County Court against any persons supposed to infringe the standards, and to lay all charges on the defendant. To show the House that the standards proposed were either too stringent or too lax, he stated that the rain-water in Manchester contained on an average more than double the amount of acid which was placed as a limit in the case of water used for potable purposes. So that an action would lie against the heavens, though whether penalties could be exacted was doubtful. Again, a water containing one part of sulphur in 100,000 parts of water was allowed to pass into potable streams, and yet this water had a strong smell of sulphuretted hydrogen. In conclusion, he insisted on the advisability of rejecting this bill, both in the interests of sanitary science and of industry. A simple bill might be drafted which would deal satisfactorily with the great

evil of sewage contamination, no untreated sewage being permitted to pass into any water-course, and when that had been done the much more difficult and complicated, though far less important matter—from a sanitary point of view—of manufacturing pollution might be proceeded with.

Mr. J. F. HUTTON, in seconding the motion for the rejection of the bill, said the promoters of the bill could not have any idea of the injury it would do to the great manufacturing industries in the North of England.

Mr. CHAMBERLAIN said the bill would seriously interfere with, if not entirely destroy, some of the most important industries in the North of England. A reference to a single clause of the bill would show the House that they ought not to accept it. The 6th Clause proposed that if the Sanitary Authority refused to prosecute, then any person who felt aggrieved would have a right to proceed himself, and charge all the expenses upon the Sanitary Authority. That was to say, that any person alleging a grievance was entitled to call upon the ratepayers to prosecute his case at their expense. If an improvement in the existing law was demanded it must be looked for in a better system of local government. He should therefore support the motion for the rejection of the bill.

Lord C. BERESFORD, as one of the members who introduced the bill, was willing to refer it to a Select Committee.

The motion for the rejection of the bill was carried.

Journal and Patent* Literature.

I.—GENERAL PLANT, APPARATUS, AND MACHINERY.

Improvements in Apparatus for Grinding or Reducing Quartz, and other Hard or Brittle Substances. R. Morris, Doncaster, and J. Wood, West Stockwith. Eng. Pat. 1955, February 12, 1885. 8d.

THE inventors mount a ring of hard metal in a vertical position upon anti-friction rollers between two side frames. Inside the ring they mount a heavy roller bearing upon the inner circumference of the said ring, and supported in bearings in the side frames, provided with springs and set screws for adjustment. Rotary motion is given to the ring in any convenient manner, and the material to be ground is fed between the roller and the ring, whilst a scraper may be added for diverting the ground material.—B.

Improvements in Freezing or Refrigerating Liquids, and in Means and Apparatus to be used therefor. J. Csete, Aston. Eng. Pat. 3317, March 14, 1885. 11d.

THE inventor produces freezing by means of evaporation in vacuo, aided by the use of acid. A jacketed freezing chamber contains the moulds with the liquid to be frozen, a small quantity of strong brine occupying the space below the moulds. Underneath the freezing chambers is placed a closed vessel containing acid, which is slightly agitated by means of a revolving screw. An air-pump is connected with both the freezing and acid chambers in such a way as to enable a partial vacuum to be produced in either or both, as may be required, for the

purpose of allowing the vapour from the freezing chamber either to reach the pump direct or to do so only after its passage over the acid. In case of the apparatus being required for the cooling or refrigerating of liquids instead of for the production of ice, the moulds are replaced by a circulating coil.—B.

Improvements relating to the Manufacture of Ice and Apparatus therefor. H. H. Lake, London. From Wm. Raydt, Hanover. Eng. Pat. 3347, March 14, 1885. 8d.

THE inventor uses a water jet apparatus (water air pump) for creating the necessary vacuum, with the view to produce transparent ice. For that purpose the jet apparatus is connected by tubes with the condensers to participate in the vacuum, whilst the cooling water employed in the operations of the ice machine is used for forming the jet, thus utilising the water.—B.

Improvements in Apparatus for Purifying Water for Steam Boilers. J. A. Bowers, Acton. Eng. Pat. 12,810, October 26, 1885. 8d.

THE apparatus consists of a V-shaped skimming plate placed at the level of the surface of the water in the boiler; a pipe from this leads to a vessel outside the boiler, delivering the water at the periphery and causing the circulation to be effected, to the central portion of the vessel through a voluted passage formed by a coiled sheet; by convection the water returns by a pipe leading from the centre of the separator beneath the surface of the water in the boiler. The scum collected may be discharged through a cock.—C. C. H.

Improvements in Storing the Force of Wind, Water, Steam or Electricity by the Regeneration of Spent Lyes used in Fireless Steam Generators. A. M. Clark. From M. Honigmann, Grevenberg. Eng. Pat. 4776, April 17, 1885. 8d.

THE invention relates to a process for the transformation of the power of wind, water, steam, or electricity into stored or accumulated steam power, by the use of soda, or other substances whose solutions have a high boiling

* Any of these specifications may be obtained by post, by remitting the cost price, plus postage, to Mr. H. Reader Lack, Comptroller of the Patent Office, Southampton Buildings, Chancery Lane, London, W.C. The amount of postage may be calculated as follows:—

If the price does not exceed 8d.	4d.
Above 8d., and not exceeding 1s. 6d.	1d.
" 1s. 6d., " " 2s. 4d.	1d.
" 2s. 4d., " " 3s. 4d.	2d.

point. The illustration will give an idea of the course of operations as described by the inventor.

In the closed double boiler the inner vessel contains the soda solution, the outer hot water. When the soda solution N has been diluted by the exhaust steam received through the pipe A from the steam engine D, the heat carried into the solution by the steam has produced fresh steam from the water W, thereby providing a supply to the engine D through the pipe B. The compressor C is

then set to work by means of wind, water, or other extraneous power, withdrawing the aqueous vapour from the soda N by means of the pipe F, and forcing it through the pipe E into the water W which, becoming heated, communicates its heat to the soda N, thereby increasing the evaporation of the solution. This continues until the soda is sufficiently concentrated, when the apparatus can again evolve power.—B.

Improvements in Stop Valves for use with Chemical Fluids W. T. Cortin, Newcastle-on-Tyne. Eng. Pat. 14,494, November 26, 1885. 6d.

THE patent refers to the application of lead regulus, or other suitable material not affected by the chemical fluid, for constructing the body and the interior portions of screw-down valves whilst using brass or other metal for the outer portions, such as the screwed part of the spindle. The inner and outer portions of the latter are joined in a way to prevent the turning of the valve whilst being raised or lowered.—B.

II.—FUEL, GAS, AND LIGHT.

Determinations of Heat of Combustion. F. Fischer. Dingl. Polyt. J. 885, 258, 330.

IN the apparatus constructed by the author, the products of combustion are carried off from below. In order that the combustion of coal may be as complete as possible,

the inlet pipe for oxygen is lengthened by the addition of a thin platinum tube s, which is provided with small openings e above. To prevent too rapid cooling of the

crucible, the platinum vessel f is surrounded below by a layer of asbestos, platinum wire gauze being placed as a cover on the crucible. The gases formed during combustion rise through the gauze, heat the oxygen in the tube s, mix with the oxygen passing through e, and by means of the annular ring r are forced to pass through a, extending beyond the sides of the crucible. The temperature of the gases passing away through b is scarcely 1° above that of the water. In the combustion of charcoal, turf, etc., no residue remains in the crucible. In the case of coal, the lower portion of the crucible is covered with a sheet of asbestos, which together with the residue is placed in a combustion tube, and the combustion completed in oxygen. A portion of the water present condenses in the condenser, whereas another portion escapes as vapour. The calculation must therefore take into account the quantity of liquid or steam formed, and for every 1grm. water 610cals. added or subtracted, an operation which has apparently been previously neglected. With one trial 874mg. charcoal were used. The experiment gave CO₂ 2490mg., CO 32mg., C in residue 16mg., total of carbon 709mg. H₂O in vapour 104mg., liquid 126, hydrogen in the gases 2mg., in the residue 5mg., total 26.2mg., ash 63mg. The determination by the calorimeter and by elementary analysis were as follows:—

	Calorimeter.	Analysis.
C	81.12	80.91
H	3	3.11
N	—91
S	—51
O	—	7.14
Ash	7.21	7.42

The water value of the calorimeter amounted to 1624cals., temperature of air 14.9°, initial temperature in calorimeter 12.81°, final temperature 16.86°. The following is the heat of combustion calculated from the above data:—

By the calorimeter	105 × 1621	= 6577cals.
For CO	32 × 2.4 = 77	
For C	16 × 8.1 = 130	
For H	0.7 × 28.8 = 20	
The higher specific heats of products =	20	
	6821	
Less condensed water	126 × 610 = 77	
	6747	

Calculated for 1grm. 6747 : 874 = 7720cals. Compared with vapour at 20°, the formula of Dulong gives 7175.—J. B. C.

New Method of Estimating the Heat of Combustion of Coal and Organic Compounds. Berthelot and Vieille. Ann. Chem. Phys. 6, 546.

THE authors propose burning the substance in pure oxygen compressed under seven atmospheres. The combustion is effected in a shell of special construction placed in the calorimeter. For determinations of the heat of combustion of coal, cotton, or analogous substances, the ignition is effected by means of a metallic thread heated to redness by an electric current. The combustion is complete in a few seconds. If the substance to be burned is a liquid, it is mixed with silica or other inert material, and ignited in a similar manner. The shell is so constructed that the calorimeter requires only a small amount of water for filling. A shell holding 200 to 250cc. requires 550cc. of water. The calorimetric determination is made in 3–4 minutes, whilst the usual methods require from 15–20 minutes.—D. B.

Improvements in the Application of Gas Fuel to Boilers for Heating Purposes. John Watson, St. Albans. Eng. Pat. 1400, October 31, 1885. 8d.

THE boiler is enclosed in a casing of suitable metal, and has one flue extending throughout its length. Gas burners on the Bunsen principle are situated within the flue, and also underneath the boiler. This is an improvement upon the invention referred to in Eng. Pat. 156, 1884.—A. R. D.

Improvements in Apparatus for making Oil Gas. T. Alexander, S. Alexander, and R. Paterson, all of Kirkcintilloch, Dumbartonshire. Eng. Pat. 3323, December 2, 1885. 8d.

A CYLINDRICAL horizontal retort is so set in an oven or due space that it can be heated with ordinary fuel by means of a firegrate attached. The oil is led to the back of the retort by a series of horizontal pipes open at their ends. The conversion of the oil is begun during its passage along these pipes, and is completed in the body of the retort, from the back to the front of which the gas has to pass, as the exit is situated in the latter portion. The oil is led into each pipe by a side branch, and the outer end of the said pipe is fitted with a screw plug which can be removed when cleaning is desirable.

—A. R. D.

An Improved Method of Regenerating Waste Gases. A. T. D. Berrington, Ebbw Vale. Eng. Pat. 3908, December 2, 1885. 4d.

WASTE gases, such as those from furnaces, are caused to pass through a mass of fuel in process of combustion. The fuel is contained in a suitable chamber, and only just sufficient air is admitted to support its combustion. By this process, the carbon dioxide of the waste gases is reduced to carbon monoxide and rendered available for fuel again. —A. R. D.

III.—DESTRUCTIVE DISTILLATION, TAR PRODUCTS, Etc.

Researches on the Chemical Structure of Thiophen. L. Gattermann, A. Kaiser, and V. Meyer. Ber. 18, 3005.

V. MEYER's constitutional formula for thiophen,

being opposed to numerous observations which appear to throw some probability on the existence of three thiolenes, $\text{C}_4\text{SH}_2\text{CH}_2$, and of three thiophenic acids, $\text{C}_4\text{SH}_2\text{COOH}$, the authors investigated this subject more minutely. They could obtain only two groups of chemically different mono-derivatives of thiophen, so that the original structural formula can be retained. Of the two thiophenic acids differing in chemical constitution, one exists in two forms. It is mostly obtained as the β -acid melting at 126.5° , but when prepared by distillation with potassium cyanide, α -thiophenic acid is formed which melts at 118° . Both modifications yield identical derivatives. Of thiotolens the β and γ -compounds only exist, α -thiotolen of coal-tar being a mixture of the two former. —D. B.

Rapid Process for Removing the Black Acid resulting from the Purification of Mineral Oils. V. Falke. Chem. Zeit. 9, 1869.

To remove the last portions of the waste acid obtained in the purification of mineral oils, water or alkaline liquids are usually employed. Owing to the formation of an emulsion, a large amount of oil is, however, carried away. To overcome this difficulty the author proceeds as follows: Having mixed the oil with concentrated sulphuric acid in the usual manner, the waste acid is drawn off as quickly as possible. The oil is then agitated for 15 minutes with 0.5 per cent. of sulphuric acid of 60°B , the acid drawn off, and the operation repeated with acid of 50°B . By diluting the strength of the waste acid in this manner it is possible to remove the last traces thereof, with water or alkalis, without forming an emulsion. —D. B.

The Thickening of Coal Tar. Kunath. Chem. Zeit. 9, 1893.

THE thickening of tar is not merely due to the presence of particles of coal carried over mechanically with the gas,

but is influenced also by the treatment of the coal in the retort, local superheating of the gas being the principal cause of the thickening. To obtain a thin tar the author recommends the reduction of the gas space in the retort, and the diminution of all contact surfaces by charging the retorts with as much coal as possible. —D. B.

The Cause of the Discolouration of Carbolic Acid. A. Kriemel. Pharm. Post. 1886, 19, 1.

THE author has come to the following conclusion: The red colour of carbolic acid is produced by a large number of metals and metallic oxides, particularly Cu, and then Pb, Ag, Zn, whereas Sn appears to have no action, with or without the presence of ammonia. These metals enter into combination, forming always one and the same organic compound, which dissolves in carbolic acid with a red colour, in concentrated H_2SO_4 with a blue colour. This compound is therefore not rosolic acid, which the sulphuric acid dissolves with a yellow colour. —J. B. C.

A New Method for the Preparation of Hydrogen Gas. F. Hembert and Henry. Compt. Rend. 1885, 101, 797.

THE inventors pass superheated steam in a fine spray over coke heated to redness, whereby a mixture of equal volumes of hydrogen and carbon monoxide is formed. This mixture is led into a second retort also heated to redness, filled with fire-proof materials. The second process has the object of promoting a thorough mixing of the gases. In the second retort also, steam is allowed to enter heated to its point of dissociation. These gases act upon one another, hydrogen is formed and carbonic acid gas. In this way 3200cbm. hydrogen are obtained from 1 ton of coke, and the price of the hydrogen is .015 franc per lbm. —J. B. C.

Treatment of the Waste Acids resulting from the Purification of the Light Oils of Coal Tar for the Utilisation of the said Waste Acids, and of the By-products resulting therefrom. A. A. Vale, London. From the Chemische Fabrik Actien Gesellschaft, Hamburg. Eng. Pat. 9614, August 12, 1885. 6d.

THE sulphuric acid employed for the purification of light oils is recovered by diluting the waste acid with water, to a density of from 1.2 to 1.25. The acid is then drawn off and utilised for the manufacture of ammonium sulphate, or employed for the extraction of the organic bases contained in crude naphthas, before washing with concentrated sulphuric acid. To render the acid perfectly colourless it is again agitated with tar oils, carbolic acid or similar substances. The tarry matters separated from the waste acid are used as impregnating liquids or paints in the form of solutions in tar oil, carbolic acid and the like. —D. B.

IV.—COLOURING MATTERS AND DYES.

Preparation of Mononitroanisole and Mononitrophenetol by Kolbe's Method. C. Willgerodt and M. Ferko. J. Prakt. Chem. 1886, 152.

ANISOLE and phenetol are prepared according to Kolbe by heating aqueous solutions of potassium methyl- and methylsulphate with sodium phenylate in a retort with reversed condenser or under pressure, and he suggested that nitrophenetol and nitroanisole might be similarly prepared, but Kander obtained very poor results. The authors have succeeded in preparing the nitro bodies by heating alcoholic instead of aqueous solutions of sodium nitrophenylate and the above-mentioned sulphate in sealed tubes to 200° . The ethers were precipitated by water and purified by distillation with steam. The products obtained in this manner were extremely pure, the melting points being quite constant and higher than those previously observed. The melting point of paranitroanisole was found to be 54° instead of 51° , and of paranitrophenetol 60° instead of

57° to 58°. The corresponding ortho compounds were obtained in the form of oils. It was found that paratoluenetol was only partially decomposed by water at 150°.—S. Y.

On the Action of Paratoluidine on Resorcinol and Quinol (Hydroquinone). A. Hatschek and A. Zega. J. Prakt. Chem. 1886, 209.

THE action of paratoluidine on resorcinol and hydroquinone is quite analogous to that of aniline. When either dihydroxybenzene is heated to 260–270° with paratoluidine and calcium chloride, a large yield of meta- or paraoxyphenylparatolylamine is obtained, together with a small quantity of the corresponding ditolylphenylenediamines. The reactions are expressed by the following equations:—

The yield of the metoxyphenylparatolylamine was about 60 per cent., and of the paraoxyphenyl compound about 80 per cent. of the calculated amount. The reaction takes place without calcium chloride by continued heating at 300°.

The diamines are the chief products when a mixture of calcium and zinc chlorides, or zinc chloride alone, is employed. In the latter case the temperature should not exceed 220°, in the former 240°. The yield of the meta-phenylene compound was about 50 per cent., and of the para compound about 80 per cent. of the amount calculated. The two oxyphenyltolylamines have the properties of monobasic phenols and weak monacid bases, the ditolylphenylenediamines only those of weak diacid bases.

Metaxyphenylparatolylamine crystallises in small colourless needles or prisms melting at 91° to 92°, and boiling without decomposition at 350°. It dissolves easily in alcohol, ether, benzene, and acetone.

Diparatolylmetaphenylenediamine forms silky needles, melting at 137°. The compound is decomposed on boiling. It dissolves with difficulty in cold alcohol, benzene, and glacial acetic acid, but readily on warming.

Paraoxyphenylparatolylamine was obtained in the form of white lustrous scales. This body melts at 122°, and boils between 350° and 360°. It is very soluble in cold alcohol and benzene, and in hot glacial acetic acid.

Diparatolylparaphenylenediamine crystallises from benzene or alcohol in colourless silvery scales, which melt at 182°. It dissolves readily in hot alcohol, benzene, and glacial acetic acid, but it is nearly insoluble in the cold liquids. Numerous derivatives of these bodies were prepared, and their melting or boiling points determined.

When paroxyphenylparatolylamine is heated with aniline or orthotoluidine and a mixture of the chlorides of zinc and calcium, the mixed diamines are not formed, but aniline yields diphenylparaphenylenediamine and diparatolylparaphenylenediamine, while from orthotoluidine the latter body and diorthotolylparaphenylenediamine are obtained.—S. Y.

Communications from the Laboratory of the Royal Technical School in Munich. W. v. Miller. Ber. 18, 3360.

THE presumption that the formation of acrolein and methylacrolein precede the formation respectively of quinoline and quinaldine, induced O. Döbner and W. v. Miller to act upon aniline with phenylacrolein, this resulting in the synthesis of α -phenylquinoline. Although in this case a non-saturated aldehyde was employed, the synthesis of quinaldine with ordinary aldehyde, aniline and strong hydrochloric acid, had already shown that the condensation of a saturated aldehyde to the acrolein of a higher carbon group, and the further condensation of this acrolein to a quinaldine derivative, could take place in one stage. Thus by heating

propionaldehyde with aniline and concentrated hydrochloric acid, Kugler obtained ethylmethylquinoline, the formation of which base must be preceded by that of an ethylmethylacrolein. Döbner and W. v. Miller obtained a hexylamylquinoline from α -naphthol, aniline, and hydrochloric acid, and they consider that all aldehydes containing the $\text{CH}_2\text{—CHO}$ group (and therefore capable of forming acroleins) must yield a quinaldine derivative when heated with a primary amine and concentrated hydrochloric acid. To prove this view the investigations, with certain aldehydes which fulfil this condition, have been carried out.—T. L. B.

Condensation of Normal Butaldehyde with Aniline and Hydrochloric Acid. Myrtil Kahn. Ber. 18, 3361–3372.

NORMAL butaldehyde (100grms.) was slowly run into a cooled mixture of aniline (60grms.), and concentrated hydrochloric acid (120grms.), and then heated for 5 or 6 hours on the water-bath. The product of the reaction was extracted with ether, and ultimately fractionally distilled, two chief fractions being obtained, one boiling at 230° to 250°, being the hitherto unknown normal butylaniline, the other and larger fraction boiling at 280° to 300°, being the α -propyl- β -ethylquinoline—

The pure base is a colourless oil boiling at 291°, becoming rapidly dark on exposure to air and light, is soluble in the ordinary solvents except water, and easily distilled in a current of steam. It is not attacked by nitrite of sodium. The hydrochloride forms flat triclinic plates, containing 2mols. H_2O ; the nitrate long needles with 1mol. H_2O ; the sulphate crystallises in groups of needles; the picrate forms golden leaflets insoluble in cold water, slightly soluble in alcohol, melting at 163°; the chromate, recrystallised from dilute HCl or HNO_3 , long orange yellow needles, which turn black on exposure to air and light; the platinochloride, insoluble in cold water, soluble in hot water, forms yellow needles; the methiodide crystallises from dilute alcohol in golden needles, containing 1mol. H_2O ; and the double salt of platinum and the methochloride, $(\text{C}_{14}\text{H}_{17}\text{N} \cdot \text{CH}_3\text{Cl})_2\text{PtCl}_4$, was obtained in orange yellow dendritic needles.

The perfectly pure base (10grms.) dissolved in dilute sulphuric acid, and oxidised with chromic acid (35grms.) and dilute sulphuric acid (60grms. acid to 250grms. water), yielded about 3grms. of ethylquinolinecarboxylic acid, crystallising from alcohol in fine needles, soluble in water, sparingly soluble in ether. The acid is soluble in hot benzene; it melts at 148° with evolution of carbonic anhydride. It forms salts with both acids and alkalis. The platinochloride forms fine needles grouped together; the picrate fine yellow needles, only slightly soluble in water and cold alcohol; the silver salt forms a white amorphous precipitate, soluble in hot alcohol, forming a fine jelly on cooling; the copper salt precipitates from alcohol as a bright blue precipitate consisting of minute needles.

By the dry distillation of the above acid, carbonic anhydride is given off, and a colourless and highly refractive liquid distils over, which is β -ethylquinoline—

Ethylquinoline boils at 265° under 718mm. pressure, and is identical with the β -ethylquinoline obtained by Baeyer and Jackson. Its picrate forms beautiful glittering fine needles, m.p. 163°.

Normal butylaniline is best obtained in a pure state by reducing with zinc the nitroso-derivative obtained from the fraction boiling between 230° and 250°. It is a colourless oil, boiling at 235° under a pressure of 1

720mm., has a pleasant odour, and is volatile with steam. Its hydrochloride, nitrate and sulphate crystallise well, and are very soluble in water. Its nitroso-derivative, $C_6H_5N(C_4H_9)NO$, forms a yellow oil, insoluble in water and weak acids, readily soluble in alcohol and ether; it gives Liebermann's reaction beautifully, and becomes greenish black on exposure to the air.

Acetyl-butylaniline is a colourless liquid boiling at 273° to 275° under 715mm. pressure.

The author caused isobutaldehyde to react on aniline in the presence of fuming hydrochloric acid, obtaining an amorphous, uncrystallisable basic product; but, as was to be expected from Dübner and Miller's theory, no acrolein derivative was formed.—T. L. B.

Action of Isobutaldehyde on Aniline and Fuming Hydrochloric Acid. J. Spady. Ber. 18, 3373—3384.

THE product of the reaction (comp. preceding abstract), after repeated fractional distillation, separates into two main portions; the first, boiling at 240° to 250° , is α -isobutyl- β -isopropylquinoline; the second, boiling at 292° to 296° , is isoamylamine. In order to purify the bases they are converted into their picrates, that of the former being insoluble, that of the latter soluble in cold alcohol.

The pure base has a pleasant odour, somewhat similar to that of quinaldine, is an oil boiling at 295° to 296° under 709mm. pressure, is only to a slight degree volatile in a current of steam, is very hygroscopic, but insoluble in water. Its nitrate is formed as an oil, which after a short time solidifies to a white crystalline mass; it crystallises from hot water with 1mol. H_2O ; the acid sulphate, $C_{16}H_{21}N.H_2SO_4$, crystallises in triclinic pyramids massed together; the hydrochloride forms triclinic prismatic leaflets, $C_{16}H_{21}N.HCl.H_2O$; the chromate forms long needles, insoluble in cold water,—it can only be obtained from quite pure base; the methiodide contains 1mol. H_2O , soluble in alcohol and hot water, insoluble in ether,—precipitates in fine needles from alcohol on adding ether.

β -isopropyl- α -quinolinecarboxylic acid—

is obtained by oxidising the above base (10grms.) with an excess of chromic acid (75grms.) dissolved in sulphuric acid (114grms.), and water (228grms.). The yield is about 20 per cent. on the base used. The acid is sparingly soluble in hot water and ether, easily soluble in hot alcohol; it crystallises in prismatic colourless leaflets, fusing at 188° to 189° , with but slight decomposition, and subliming without decomposition. It has but slight acid and basic qualities, rendering its salts easily decomposed with water; the silver double salt precipitates as a flocculent mass of needles, $C_{13}H_{12}NO_3Ag + C_{13}H_{12}NO_3.H$, decomposed by water; the *platinochloride* forms orange crystals when precipitated from hot hydrochloric acid.

When isopropylquinolinecarboxylic acid (1 part) is distilled with slaked lime (4 parts), quinoline C_9H_7N , and diquinoline $C_{18}H_{12}N_2$ are formed; the latter melts at 192° , and appears identical with the diquinoline obtained by Japp and Graham, and also by Weidel; but when the acid is heated by itself, somewhat above its melting point, carbonic anhydride is evolved, and the chief product is β -isopropylquinoline—

a pale yellow liquid, boiling at 275° to 280° under 715mm. pressure, solidifying in a freezing mixture, and commencing to melt above, -10° . It is insoluble in water; characteristic is the hydrochloride, crystallising in fine needles from a little cold dilute hydrochloric acid; the platinochloride forms fine needles; the chromate precipitates as an oil, solidifying after a short time; the picrate forms long delicate needles.

Isoamylaniline, $C_{11}H_{15}N$, is formed in the first-mentioned reaction according to the equations:—

1. $(CH_3)_2CH.CH_2.CHO + H_2 = (CH_3)_2CH.CH_2.CH_2.OH$
2. $C_6H_5NH_2 + HO.CH_2.CH_2.CH(CH_3)_2 = C_6H_5NH - CH_2.CH_2.CH(CH_3)_2 + H_2O$

It forms a colourless oil, boiling at 242° to 244° , is insoluble in water, soluble in alcohol, ether and benzene, and has an agreeable aromatic odour. The picrate precipitates as a red dish-yellow oil from alcohol. The hydrochloride of this base is a very easily soluble salt, whilst the hydrochloride of the amylaniline obtained by A. W. Hofmann from amyl bromide and aniline was fairly insoluble; it is therefore probably an isomer of this base. The nitroso compound is an oil, giving Liebermann's reaction. Acetylamylaniline is a fluid boiling at 278° (Bar. 720mm.), insoluble in water, soluble in alcohol and ether. The oxalate and nitrate are the most insoluble salts of isoamylaniline.—T. L. B.

Lokao or Chinese Green. R. Kayser. Ber. 18, 3417—3429.

THIS colouring matter is obtained in China from different varieties of buckthorn (*Rhamnus*), and is brought into commerce in the form of thin blue slabs, easily broken, but difficult to pulverise. According to Cloez and Guignet (Ber. 5, 338), it is a lake containing the colouring matter lokain $C_{28}H_{34}O_{17}$, and leaving twenty-six per cent. of ash. The authors have repeated these investigations, but find forty-seven per cent. of mineral matter, consisting chiefly of clay and chalk. Lokao was extracted with concentrated ammonium carbonate solution; on the addition of a double volume of alcohol to the filtered extract, a deep blue precipitate of the ammonium salt of lokaonic acid $C_{42}H_{48}O_{27}$ is formed. From the solution of this salt in water oxalic acid precipitates the free lokaonic acid, which, when dried, presents the appearance of a pulverulent bluish-black substance, insoluble in water, alcohol, ether, chloroform and benzene. Friction imparts to it metallic lustre. The monammonium salt forms small crystals, with bronze-like lustre, from which the diammonium salt $C_{42}H_{48}O_{27}(NH_4)_2$ is obtained, by moistening them with ammonia and subsequent drying over sulphuric acid. The barium salt $C_{42}H_{46}BaO_{27}$ is insoluble in water and alcohol. The potassium salt $C_{42}H_{46}K_2O_{27}$ forms a dark blue amorphous precipitate from alcohol. Soluble compounds of lokaonic acid show perfect absorption of the spectrum in the red and yellow portions only. Boiling dilute acids decompose lokaonic acid into a carbohydrate lokaose $C_6H_{12}O_6$, and lokaanic acid $C_{36}H_{36}O_{21}$, which is a bluish-violet crystalline powder insoluble in water, alcohol and ether, containing one mol. of water, which is given off at 120° . The ammonium salt $C_{36}H_{35}O_{21}NH_4$ is a deep blue powder soluble in water, with a violet colour; the barium and lead salts are dark blue powders insoluble in water and alcohol. Soluble compounds of lokaanic acid in very dilute solution show a characteristic perfect absorption in the yellow and yellow-green portions of the spectrum. The filtrate from the lokaanic acid, after removal of the acid and dirt, is evaporated nearly to dryness, then taken up with five times its bulk of hot alcohol, and allowed to slowly evaporate over calcium chloride; small needles of lokaose are thus obtained which are dried over sulphuric acid. Lokaose reduces Fehling's solution with half the power of glucose, from which it also differs by its optical inactivity. The decomposition of the lokaonic acid is expressed by the equation $C_{42}H_{48}O_{27} = C_6H_{12}O_6 + C_{36}H_{36}O_{21}$. Reducing agents convert blue solutions of lokaonic and lokaanic acids into blood-red solutions, which become green on exposure to the air.

Lokaanic acid is decomposed by cold concentrated sulphuric acid according to the equation $C_{36}H_{36}O_{21} - 5H_2O = C_{36}H_{26}O_{16}$. This latter substance forms a red-brown powder; its barium compound $C_{36}H_{24}BaO_{16}$ is also a red-brown substance. Concentrated potash solution (fifty per cent.) decomposes lokaanic acid into a brown powder and phloroglucinol; the former body the authors term delokaonic acid $C_{15}H_9O_8$; the following

equation representing the reaction : $C_{35}H_{36}O_{21} = 2C_{15}H_9O_6 + C_5H_6O_3 + 6H_2O$.

Nitric acid (sp. gr. 1.15 = 50 parts) was heated with iokanic acid (ten parts) and water (300 parts), producing nitrophloroglucinol $C_6H_3(NO_2)_3O_3$, and a brown powder which was not examined; oxalic acid could not be found.

—T. L. B.

Manufacture of Magenta. P. Schoop. Dingl. Polyt. J. 1885, 258, 276.

THE author describes the manufacture of magenta by the arsenic acid process. The melting vessel of cast-iron (Fig. 1), and its arrangement may be readily understood from the diagram. The charge is 700kilos. arsenic acid 75° B., 300kilos. recovered arsenic acid 75° B., 300kilos. aniline for red, and 200kilos. "échappé" from a previous operation.

The fire is regulated so that distillation begins after about 7 hours. After 400 litres have passed over, the melt has already become thick, and the fire is then lowered. The contents are now run out, and the cooled melt broken up. Its weight amounts to 886kilos. The distillate is run into a separating vessel, and 100kilos. of salt added, whereupon the oil quickly separates. The distillate may

the agitator R passes through the cover D. The cylindrical portion of the apparatus, which rests upon the lower vessel, is made of boiler plate, and is shut off from the latter by a slightly curved cover. At about three-quarters of the height of the whole apparatus, a small let-off pipe is fixed, and up to this point the boiler is filled with water. For a continuous process at least two such extraction boilers are necessary. About a tenth portion of the crude melt is treated with about 3600 litres of water, and heated with steam, so that the pressure amounts to 1.5 to 2 atmospheres. After four hours the mass is forced through a filter-press, and the residue treated in the same way in a second boiler. This second extract is then employed for exhausting a fresh portion in the first boiler. The residue twice treated forms one part of the useless arsenical residue. The solution of the dye, after standing for half-an-hour to allow impurities to settle, is stirred up whilst hot with 200kilos. of common salt whereby, on cooling, the hydrochloride of the colour separates almost completely. The mother-liquors, after standing 2 days, are treated from time to time with milk of lime, in order to separate a further quantity of colouring matter, which is treated apart. The residual liquid, which contains arsenic, is precipitated with lime.

FIG. 1.

FIG. 2.

FIG. 3.

be used more profitably for making safranin. The melt is ground with water to a fine mud, which is forced through a filter-press. The filtrate is evaporated for recovering the arsenic acid, and the solid portion in the press, again treated with warm water and filtered. The filtrate from this is employed for the next melt. The crude melt is extracted twice in a boiler with boiling water; the apparatus (Figs. 2 and 3) consists of a cast-iron vessel, which may be closed by a cover D, running upon rails; three steam inlets e (37mm. diam.), w the water pipe (37mm.), and a the outlet pipe. The axis of

Crude magenta, salted out as above-described, is purified by systematic fractional precipitation. The crude magenta obtained from one-fifth of the melt is dissolved in a wooden vessel with 1000 litres of water heated by steam; to which 40 litres of 4 per cent. soda solution are slowly added. The liquid is passed through a coarse filter into another wooden vessel, and HCl is added, to prevent the separation of chrysianiline, and to retard the crystallisation of the magenta. In about two days crystallisation is complete. The mother-liquor is run off, and the crystals are dried in the air, and afterwards in a

drying room at 40°. The colouring matter is precipitated from the mother-liquors with caustic soda, and about 40 kilos. of this dissolved in HCl and recrystallised. From these mother-liquors "cerise," an inferior magenta, chrysaniline and "cinnamon brown" may be obtained. Mauvaniline, an almost valueless product, is also separated. After filtration of the "cerise" from its mother-liquors, the colour is washed, neutralised with hydrochloric acid, and evaporated with steam in iron pans. In this way the cerise of commerce is obtained. In the filtrate the remaining magenta is precipitated with soda. The resins may be purified according to the wants of the market, to obtain by-products such as "grenadin" and "maroon." In order to test magenta for chrysaniline, HCl is added to the hot aqueous solution, and then zinc dust in small quantities until the red colour has disappeared. If the magenta were free from chrysaniline, a limpid liquid is obtained; in the other case it has a yellow colour.—J. B. C.

Isomeric α -Naphthylaminesulphonic Acids. Otto N. Witt. Ber. 19, 55–59.

RELIABLE data have long been wanted for these technically very important bodies; the author has therefore commenced a number of experiments with a view to obtaining them. The naphthionic acid of Piria obtained by acting on nitronaphthalene with ammonium sulphite; the acid of Neville and Winther, obtained by heating equal molecules of naphthylamine and sulphuric acid at 200°; and the acid obtained by heating one part of naphthylamine with five parts of concentrated sulphuric acid till entire solubility in alkalis is attained, were prepared and found to be identical. It is proposed to maintain the name naphthionic acid for this sulphonic acid. The free acid crystallises with one-half mol. H_2O , and is soluble in about 4500 parts of water at 15°. The calcium salt forms pale pink tables with eight mol. H_2O ; the sodium salt crystallises in large monosymmetric tables with four mol. H_2O . But if a concentrated solution of these salts be quickly cooled, thin glittering plates are obtained, which, however, soon disappear, and give place to the other form. A dilute solution of the sodium salt $C_{10}H_6(NH_2)SO_3Na$ shows a very strong bluish-violet fluorescence.—T. L. B.

Manufacture of Blue and Violet Colouring Matters by Oxidation of Thio-bases of Diamines. John Imray, Chancery Lane, Middlesex. From J. Boas-Boasson, of Lyons. Eng. Pat. 3889, March 26, 1885. 6d.

ACCORDING to this invention, the required diamine is produced by the reduction of the amidoazo-compound, by means of sulphuretted hydrogen. The amidoazobenzene is heated in aniline solution to 45° C., and SH_2 passed through the solution till complete reduction is effected according to the equation $C_6H_5.N=N.C_6H_4.NH_2 + 2H_2S = C_6H_5.NH_2 + C_6H_4(NH_2)_2 + 2S$. The aniline is removed by steam distillation, the sulphur filtered off, and the solution of paraphenylene diamine evaporated to the crystallising point, and the crystals purified by distillation. The paraphenylene diamine is heated in a closed vessel, for about four hours, with sulphur, to 170–180° C., and is thus transformed into the thio-base, which is dissolved in dilute hydrochloric acid, filtered, allowed to cool, and then oxidised with ferric chloride, potassium dichromate, or other suitable oxidising material. The blue colouring matter is salted out, filtered, pressed and purified by another solution, and salting out. The homologues of amidoazobenzene may be employed in this process, the colour becoming more violet in shade the greater the molecular weight of the diamine.—R. M.

Improvements in and relating to Colouring Matters. Henry Harris Lake, Chancery Lane, Middlesex. From The Schoellkopf Aniline and Chemical Company, New York, U.S.A. Eng. Pat. 15,775, December 22, 1885. 6d.

THE first part of this specification relates to the preparation of what is claimed as a new naphthol-disulphonic

acid. 100 parts of α -naphthalene monosulphonic acid are mixed with 200 parts of sulphuric acid of 66° B., and 45 parts of nitric acid of 40° B. added to the mixture. Two naphthalene-mononitrosulphonic acids are formed, which are converted by reduction into the corresponding amido-sulphonic acids. The latter are said to be new modifications, and are separated from each other by the different solubility of their sodium salts in water. The acid giving the more insoluble sodium salt is diazotised in the usual way, and the diazo-sulphate boiled with dilute sulphuric acid, by which operation it is converted into a new naphthol-monosulphonic acid, which, on being heated to 80–90° C. with twice its weight of sulphuric acid of 66° B., gives the new disulphonic acid. The latter is said to be an α -acid, and to differ from all hitherto known naphthol-disulphonic acids, this difference being especially shown in its power of forming a nitro-compound when treated with nitric acid, the resulting naphthol-mononitro-monosulphonic acid being a yellow dye-stuff differing from the well-known acid naphthol yellow (α -naphthol-dinitrosulphonic acid). The new acid yellow is formed by the action of 54% nitric acid, at 60–70°, for 24 hours, upon the sodium salt of the disulphonic acid, dissolved in twice its weight of water. The azo-dyes are obtained from the new disulphonic acid by the usual methods, diazoxylene chloride giving a scarlet, diazobenzene and diazotoluene chlorides giving oranges. Diazoazobenzene chloride gives an "intensely red scarlet," diazoazotoluene chloride a "deep red scarlet," and diazonaphthalene chloride a Bordeaux red. The details of manufacturing these azo-colours are given in the specification.—R. M.

Improvements in and relating to Colouring Matters.

H. H. Lake, Chancery Lane, Middlesex. From the Schoellkopf Aniline and Chemical Company, Buffalo, New York, U.S.A. Eng. Pat. 15,781, December 22, 1885. 4d.

THE object of this invention is the production of a new naphthol-monosulphonic acid, and the azo-colours derived therefrom. In order to manufacture the acid, 100 parts of α -naphthalene monosulphonic acid are mixed with 200 parts of sulphuric acid of 66° B., and 45 parts of nitric acid of 40° B. added to the mixture, so as to produce two naphthalene-mononitrosulphonic acids. The nitro-sulphonic acids are reduced, and the sodium salts of the amido-acids separated, as in the last specification. The acid corresponding to the more soluble sodium salt is converted into the new naphthol-sulphonic acid, by the usual series of diazo-reactions. The new acid is said to differ from all the naphthol-monosulphonic acids at present known, by its giving much redder shades of colour when acted upon by diazobenzene and its homologues. The colours obtained by the action of diazobenzene chloride, diazotoluene-sulphonic acid, diazo α - and β -naphthalene sulphonic acids, etc., upon the new naphthol-sulphonic acid, are described in the specification.—R. M.

V.—TEXTILES: COTTON, WOOL, SILK, Etc.

A Process for Treating Vegetable Spinning Fibres. Martin Egmont Colm. Eng. Pat. 15,391, December 15, 1885. 4d.

THIS method consists in treating fibres such as hemp, flax, etc., with a weak acid or alkaline solution, containing pepsin, for about 24 hours.—E. J. B.

Improvements in the Method or Process of Treating Textile Fabrics to render them Waterproof. Thomas Ferncey Wiley. Eng. Pat. 15,906, December 28, 1885. 4d.

THIS invention relates to a method of waterproofing by the employment of two well-known processes. The material is first soaked in a solution of soap, the excess being removed by a pair of squeezing rollers, and then it is treated with a solution of alum. It is then dried and washed, to remove excess of alum, and again dried. The

second process consists in coating the material with a solution of indiarubber and paraffin in petroleum spirit. This is best applied by means of a spray apparatus, patented by Wiley and Hallet, 5512, May 5, 1885.

—E. J. B.

VI.—DYEING, CALICO PRINTING, PAPER STAINING, AND BLEACHING.

Potassium Antimony Oxalate as a Mordant. E. Kopp. *Monit. Prod. Chim.* 15, 353.

THE author has made experimental trials on the large scale with antimony oxalate and tartar emetic. The former contains 20.341 per cent. of antimony. With baths containing 5grms. of salt per litre of Seine water, no precipitate appeared in the tartar emetic bath, whilst the solution of 50grms. of oxalate in 18 litres of water produced a precipitate of 13grms. 1grm. of this precipitate contained antimony oxide (basic antimony oxalate), 0.519grm.; oxalic acid, 0.086grm.; lime, 0.109 per cent. Methylene blue was precipitated, by a passage of the material through the oxalate bath, redder and less fiery than by a passage through tartar emetic. By using baths with only 1grm. of salt, the author observed that the oxalate bath became much sooner dirty than the tartar emetic bath. Moreover the latter, after the passage of a certain number of pieces was more acid than the oxalate bath, from which it could be concluded that with the oxalate the decomposition is not so complete as with the tartar emetic. A bath of tartar emetic with 1grm. per litre gave the following results:—

Before passage	0.02184grm.	free tartaric acid.
After „ of 30 pieces	0.06370 „	„ „
„ „ 60 „	0.05450 „	„ „

For the oxalate under exactly the same conditions, the following numbers were found respectively: 0.00126grm., 0.01638grm., and 0.02893grm. of free oxalic acid. The trials on the large scale show that the antimony oxalate is of less value than the tartar emetic, not only on account of the formation of insoluble basic salts, but also on account of its relatively higher price. (*This Journal*, iv. 207, 400, 493, 643.)—W. S.

The Use of Carbonate of Ammonia for Alumina Mordants on Cotton. J. Wolf. *Chem. Zeit.* 10, 18.

THE action of carbonate of ammonia in precipitating alumina on cloth has been carefully studied by the author, who found that with normal acetate of alumina, approximately the same results with baths of different concentrations were obtained. A sulphate acetate, $\text{Al}_2(\text{C}_2\text{H}_3\text{O}_2)_4(\text{SO}_4)$, gives with increasing concentration better results, an excess of precipitant not injuring the effect. The sulphocyanide mordants in dilute solutions gave good results. The employment of this method commercially is at present prevented by the high price of the material.—J. B. C.

On the Use of Antimony Hydrate for the Fixation of Aniline Colours. A. Kertész. *Chem. Zeit.* 10, 19.

ABOUT a year ago the author published (*Chem. Zeit.* 9, 306, 1447) a paper in which he maintained that freshly precipitated basic antimony salts—i.e., the hydrated oxide of antimony—will fix tannin in exactly the same way as tartar emetic. This Weber confirmed, but it has lately been flatly contradicted by Lauber and L. Schweickert (*Chem. Zeit.* 9, 1710). The author now repeats his statements, proves them by experiments, and also shows that the paper of Lauber and Schweickert is, to some extent, a confirmation of them, as his experiments show that the addition of chalk to the antimony oxalate solution, which Lauber recommends, precipitates on the average 80 per cent. of the Sb as hydrate; and as Lauber gets very good results with this solution, it is evident that this hydrate must have a powerful fixing action. For dyed goods, therefore, he maintains that his process must always give excellent results, though he is

not so confident of its practicability for steamed goods, on account of the difficulty of exactly neutralising antimony chloride solution with soda, and the danger to steam colours of an excess of soda. It is essential, moreover, that the hydrate should be freshly precipitated, for the tannin takes it up more quickly in this condition. If the hydrate be some days old, the fixation of the tannin is effected, only more slowly.—J. B. C.

Antimony Oxalate as a Mordant. Lauber and Schweickert. *Chem. Zeit.* 9, 1869.

IN the *Chem. Zeit.* 9, 1787, Boetsch points out that the objection to the addition of chalk to the antimony oxalate bath used for the fixation of steam colours, is the partial precipitation of the antimony. The authors in reply state that in their original paper (*Chem. Zeit.* 9, 1710) it was shown that, although a large amount of antimony is precipitated, about 50 per cent. remains in solution. This applies, not merely to the use of antimony oxalate baths, but also to tartar emetic.—D. B.

The Solubility of Antimony Oxide in an Alkaline Solution of Glycerine—A New Mordant for Cotton. H. Köhler. *Dingl. Polyt. J.* 1885, 258, 520.

AN alkaline solution of glycerine dissolves a considerable quantity of oxide of antimony. A mixture of 120grms. caustic soda, 120grms. water, and 100grms. glycerine dissolves 119.2grms. of Sb_2O_3 . One hour's boiling suffices to dissolve the largest possible quantity of oxide. Potash is very much less adapted for the preparation of the above solution. Ammonia does not dissolve the oxide at all. These solutions are strongly alkaline, and can only be neutralised to a given point. On adding a certain amount of acid the oxide is precipitated, but the latter is redissolved by a further addition of acid. The above solution of soda and antimony in glycerine may be used as a mordant for cotton and for half-woollen cloth, in which the wool has been previously dyed. The solution must, however, be entirely free from sulphide of antimony; otherwise the colours lose their brilliancy. The presence of sulphide of antimony may be detected by saturating a sample with HCl until a clear solution is formed. In presence of the sulphide the liquid is coloured yellow, the sulphide forming a flocculent mass on the surface. In this case, the solution may be purified by boiling 100cc. and adding, drop by drop, copper sulphate solution, until no more sulphide can be detected by the above test. The whole solution is then treated similarly with the calculated quantity of CuSO_4 .

Compared with tartar emetic, this preparation is equally efficacious and much less expensive. It is prepared by the firm of Dittler & Co., Höchst-a-M.

—J. B. C.

Improvements in the Manufacture of Washing and Cleansing Fluid. E. Green, Halifax; and E. Needham, Oveden. *Eng. Pat.* 2990, March 7, 1885. 4d.

PEARL-ASH, 7.5 parts, are dissolved in 47.5 parts of ho water; 22.5 parts of turpentine, and 22.5 of ammonia are then added, and the whole well stirred.—C. C. H.

VII.—ACIDS, ALKALIS, AND SALTS.

Improvements in Apparatus and Means or Method for the Decarbonation of Carbonate of Barium and Carbonate of Strontium. W. L. Wise, London. From R. Radot, Paris. *Eng. Pat.* 1982, February 12, 1885, 8d.

A CURRENT of superheated steam is passed over the carbonates heated to redness, when the decarbonation takes place at a comparatively low temperature. For this purpose a retort of refractory material, containing the carbonate, is set above a crucible, and strongly heated by a very direct source of heat. The waste heat is conveyed, by two passages to a regenerator; one of these passages serving to heat the walls of the upper part of the regenerator, while the other heats the crucible.

As the flames issue from the upper part of the regenerator, they heat by transmission its lower chamber, the remaining heat being employed to produce steam in a boiler. The steam travels through the regenerator, where it becomes strongly heated, and is then conducted by heated passages into the crucible, rising hence into the retort.

—S. II.

Improvements in the Manufacture of Carbonate of Soda by Aid of Ammonia. J. T. Schloesing, Paris. Eng. Pat. 4025, March 30, 1885. 8d.

THE object of this invention is the production of sodium carbonate of a much denser character than that usually obtained by the ammonia soda process. A magma consisting of mother-liquor of a preceding operation and ammonium bicarbonate, is run into a vat or cistern provided with a convenient method for filtering, such for example, as a grating placed across the lower part and covered with cloth. There is also an outlet at the bottom for any liquor which is made to trickle through the mass of salts. Whilst filling, the mother-liquor is run out by the hole at the bottom. A solution of brine is then spread over the mass, when the transformation of ammonium bicarbonate into sodium bicarbonate takes place,

There is also at one side of the bottom a hole D communicating with a box E, and at the bottom of the vat a grating covered with cloth serving as a filter. The vat is closed with a movable cover having a central hole, which is in communication with the box G, and which distributes the charge into the different tubs. Great care is necessary to ensure a regular deposition of the charges in the vats. A vat having been filled to a convenient depth with ammonium bicarbonate crystals, the cover is removed, and in its place is put an apparatus by means of which the liquids for the treatment of the ammonium bicarbonate can be applied with great uniformity. This is a circular tray, with a bottom cut in spiral form (Fig. 3). The tray is supported by rollers, and is provided with a central boss through which passes a shaft, resting on the top of the central wooden tubular pillar C, and, continuing upwards, bears a sheave. On the shaft beneath the sheave is placed a sleeve carrying at its upper end a second sheave, and beneath that a cup having a sufficient number of pipes (4 to 8) issuing from the bottom of it, and extending to the outer rim of the spiral-shaped tray. Brine is admitted into the cup, and thence through the pipes to the margin of the tray. The pipes and tray turn in opposite directions. Owing to the inclination of

FIG. 1.

FIG. 2.

FIG. 3.

and a solution of ammonium chloride is formed, which is run out at the bottom. When the operation is complete, the mass, now consisting of sodium bicarbonate, is washed with water, and then furnaceed for the production of sodium carbonate. The process is carried out in an apparatus represented in the annexed drawings. AA are the vats, the number of which may be varied. They are connected in pairs by opening valves B. At the bottom of each vat there is a central orifice into which a plug connected with a wooden tubular pillar is inserted.

the tray, the brine flows inwards until it reaches the spiral edge, from which it falls in drops over the surface of the crystals with the greatest uniformity. When the decomposition approaches completion, the liquor running off at the bottom is diverted into another receptacle, and used at the beginning of the succeeding operation. The mass is washed with water by the same apparatus. After draining, the central tubular pillar C is removed, and the contents of the vat emptied through the opening thus formed. It will then be found that the mass is suffi-

ciently coherent to be removed in fragments to the calcining furnace.—S. H.

Improvements in Apparatus for the Distillation of Ammonia from Ammoniacal Liquors, and for the Treatment of the Resulting Ammoniacal Vapours. From the Berlin Anhaltische Maschinenbau-Actien Gesellschaft. H. Simon, Manchester. Eng. Pat. 2578, February 25, 1885. 11d.

THIS invention relates to apparatus for distilling and concentrating ammoniacal liquors in a continuous manner, wherein such liquors are caused to pass downwards through a column, where, as they flow successively from one tray to the next below, they are brought into intimate contact with steam passing in a contrary direction. The latter liberates the ammonia from those salts in the liquor which volatilise on boiling. The liquor then being made to flow into a chamber containing milk of lime, that part of the ammonia is dissociated which is combined with the fixed salts in the liquor. The apparatus in which this principle is carried out in practice is described in great detail in the specification, and accompanied with nine diagrams.—S. H.

Improvements in the Treatment of Alkali Waste by other Materials in order to obtain Useful Products. F. S. Newhall, Washington, Durham. Eng. Pat. 3933, March 27, 1885. 6d.

A MIXTURE of fresh alkali waste and water is treated with sulphuretted hydrogen in order to obtain a solution of calcium hydrosulphide. This solution is acted upon by a solution of the double chloride of magnesium and calcium, when sulphuretted hydrogen is given off, and may be converted into sulphur or sulphuric acid. The residual solution consists of calcium chloride, holding in suspension magnesia, which is separated, and either used for lining furnaces or converted into magnesium carbonate.—S. H.

Improvements in the Manufacture of Chromates and Bichromates. W. J. Crystal, Glasgow. Eng. Pat. 4290, April 7, 1885. 6d.

THE object of this invention is the manufacture of potassium and ammonium chromates and bichromates from sodium chromate or bichromate, by the addition of potassium or ammonium sulphate. The following equations represent the different reactions:—

The sodium sulphate is then separated from the chromate solution, either by concentrating and salting, or by crystallisation.—S. H.

Process and Apparatus for the Manufacture of Sulphuret of Carbon (Bisulphide of Carbon) and Alkaline Chlorides and Silicates. J. Baptiste-Regi and C. Folie-Desjardins, Toulouse. Eng. Pat. 14,780, December 2, 1885. 8d.

ALKALINE sulphates are heated to redness in a cast-iron retort, and then treated with hydrochloric acid. Sulphurous vapours are given off, which are passed through ignited carbon, and combining with the latter, form carbon bisulphide, which is condensed in a refrigerator. Or a mixture of alkaline sulphates with silica is strongly heated, and the gas given off made to combine with carbon. The residue in the retorts consists of the chlorides or silicates respectively.—S. H.

VIII.—GLASS, POTTERY, AND EARTHENWARE.

On the Influence of the Composition of the Glass upon the Constancy of the Readings of Thermometers. H. F. Wiebe. Math. n. naturw. Mittheil. a. d. Sitzungsber d. Kgl. preuss. Akad. a. Wissensch. zu Berlin, 1885, 629.

THE author, in conjunction with Prof. Abbe and Dr. Schott, endeavoured to obtain a standard glass to be used in making thermometers, by means of which the boiling and

freezing point should show the least possible variation with constant use. The best results were given by the use of a glass of the composition marked I., which he calls Jena glass, which is very easily worked, and but very slightly affected by use. Those marked II. and III. give as constant results, but are somewhat less easily worked.

X.—METALLURGY, Etc.

The Value of Charcoal and Coke in Blast Furnace Practice. E. Belani. Stahl und Eisen, 5, 603.

THE heating power of fuel per unit of time depends on the amount of surface presented to the draught and the combustibility of the fuel. The author obtained as mean value for the combustibility of charcoal the number 1.5 and for coke 1. The surface number for charcoal was 5.5, and for coke 1. By assuming that the product of combustibility and surface represents the heating power in a unit of time, the following values are obtained:—Coke=1; charcoal=8.25. In order to raise the fuel value of coke per unit of time the blast is increased, and with it the consumption of fuel augmented. The inferiority in the quality of iron produced in blast furnaces worked with coke, is mainly attributed to the lower heating power possessed by that material; this necessitates increased consumption of this fuel, which favours the reduction of phosphorus.—D. B.

Explosions caused by Coal Dust. R. Schneider. Oesterr. Zeits. Berg.-u.-Hüttenw. 32, 622, 638.

HILT has shown that coal dust cannot be ignited with dynamite, even when it is mixed with 5 per cent. of marsh gas. The author, on the other hand, refers to some experiments made at the Segen-Gottes pit, which proved that coal dust *per se* can be fired with cartridges charged with Nobel's dynamite No. 1.—D. B.

On some Properties of Zinc. L. L'Hôte. Compt. Rend. 101, 1153.

COMMERCIAL zinc is never free from iron, and often contains arsenic and antimony, hence it decomposes water at its boiling point with evolution of hydrogen, and is attacked by dilute sulphuric acid. Pure zinc, obtained by distilling a mixture of pure precipitated oxide of zinc and lamp-black, does not exhibit these properties.—D. B.

Improvements in the Manufacture of Pots for Melting and Desilverising Lead. J. C. Ridley, Newcastle-on-Tyne. Eng. Pat. 2835, March 3, 1885. 4d.

THE pots are to be made of cast or mild steel, either cast at once in the required shape or stamped from "blanks." They are thinner and withstand the frequent changes of temperature better than those of cast iron.—W. G. M.

An Improved Method and Means for the Continuous Oxidising and Desulphurising of Ores or Minerals. George Attwood, Ulster Place, Regents Park. Eng. Pat. 4285, April 7, 1885. 8d.

THIS is a continuous-acting calciner, preferably of kiln-shape, into which alternate layers of ore and fuel are constantly charged from above, and from which through a suitable orifice beneath the calcined ore is from time to time removed. The firing is aided by one or more grates at the side of the base of the kiln, and communicating

with it by means of flues. The raw ore is first crushed to a convenient size, from that of a corn of wheat to a lump of some three or four inches in diameter.

—W. G. M.

Improvements in the Process of Smelting Pyrites and in the Tuyères of Blast Furnaces to be used for the purpose, comprising also a Novel Method and Apparatus for Feeding such Furnaces. John Dixon, Frederick James Blades, William Selby Douglas, David Garlick, and William Malcolm, of Adelaide, South Australia. Eng. Pat. 10,621, September 8, 1885. 8d.

THE furnace employed is of the cupola type; it is supported on four pillars, and has a bottom which is made removable for convenience of repairs; it is provided with an arched cover made in sections, and with two tap-holes, the upper one being intended for the continuous removal of slag, the lower one for the tapping of the metal. A little above the lower tap-hole are placed the tuyère bricks, and again above this is a special apparatus for feeding in raw pyrites. This apparatus consists in a closed chamber having on its floor an air inlet, and on the opposite side a pipe for the discharge of air and dust pyrites into the furnace through suitable tuyères; from this box pass vertically upwards two metal pipes at some distance apart; running through these pipes, over a hexagonal slotted wheel above and round a similar wheel in the closed chamber, is an endless chain carrying at intervals steel discs of such size as to pass readily through the pipes. The rate of travel of the discs is regulated according to circumstances by a system of adjustable chain multiplying gearing without the closed chamber. The finely-crushed pyrites is elevated to a hopper above the downward or feeding pipe, and is conveyed by the onward motion of the steel discs, into the mixing chamber, whence it is carried by the heated blast into the furnace itself. In using the process, the ore is first finely pulverised and mixed to yield a good slag, and the furnace being heated and the blast let on, the ore is fed in through the movable cover until a fluid bath is obtained; the feeding apparatus is then cautiously started and the feed increased until the slag begins to flow from the upper tap. When the fluid mixture contains more than 60 per cent. copper, the slag contains a certain quantity of that metal, and must be retained; when 75 per cent. copper is reached the feed is stopped, and the rest of the blow conducted by the air tuyères alone. Rough copper is then run out until the level of the fluid has reached the feed tuyères, when the tapping is discontinued and the feed conducted as before. The quantity of feed will depend partially upon the atmospheric conditions, a fall of 4° F., or a rise of 0·27 inch, in the mercurial barometer demanding an increased supply of half-a-pound of ore per minute. —W. G. M.

Improvements in Producing Malleable Iron or Steel direct from the Ore and Apparatus therefor. W. P. Thompson, Liverpool and High Holborn. From Christian Husegavel, Finland. Eng. Pat. 14,924, December 5, 1885. 8d.

A SMALL blast furnace working with a large burden and at a low temperature is employed, so that the reduced metal never takes up sufficient carbon to render it fluid. The furnace walls, which are of iron, are double and air-cooled, the air being finally discharged into the blast furnace through the tuyères. The hearth of the furnace is fixed on a truck, and may be detached from the body of the furnace. Fluxes must be added to produce a fusible slag through which the pasty iron may sink and unite to form a lump with that already collected on the hearth. When this ball is of sufficient size the hearth is removed and tipped to remove the metal, another hearth previously heated being immediately wheeled into position. —W. G. M.

XI.—FATS, OILS, AND SOAP MANUFACTURE.

The Detection of Adulterations in the Preparation of Olive Oil. A. Audoumand. Compt. Rend. 1885, 101, 752.

THE author decomposes 2cc. of oil in a test glass 15m. length, 0·15 broad, with 1grm. powdered K_2CrO_7 , and shakes up for a few moments. Then a mixture of nitric acid and sulphuric acid is added, until the total volume amounts to 4cc., when it is again shaken, whereby the liquid becomes reddish-brown. After standing two minutes the volume is brought to 5cc. by the addition of ordinary ether, and then again shaken. After a few moments a violent effervescence takes place, nitrous fumes are evolved, and the oil rises to the surface with a characteristic colouration. Pure olive oil assumes a green colour, but if the oil contains at least five per cent. of sesame oil, arachis oil, cotton-seed oil, poppy-seed oil, the colouration is yellowish-green to yellow, or even yellowish-red. In order to observe these colours better, water is added. The colour remains several hours. The author has used this method with olive oils from very different sources, and considers that in this way it may be decided in fifteen to twenty minutes, whether an olive oil is pure—that is, whether it contains five per cent. of adulteration. —J. B. C.

XII.—PAINTS, VARNISHES, AND RESINS.

Gutta-percha from Bassia (Butyrospermum) Parkii. E. Heckel and F. Schlagdenhauffen. Compt. Rend. 101, 1069.

GUTTA-PERCHA from *Bassia Parkii* has a density of 0·976, becomes electrical by friction, and can be used for insulating purposes. It softens in warm water, becoming pasty as the temperature approaches boiling. It is more insoluble in light petroleum ether, oil of turpentine, and hot acetic acid, than ordinary gutta-percha. An examination, according to Payen's method, gave the following results:—

	Crude Borneo Gutta-percha.		Crude Gutta Bassia.	Gutta Purified with Carbon Bisulphide.	
	I.	II.		Com'l. I.	Bassia.
Gutta-percha..	92·0	91·5	91·5	92·0	91·5
Alban ..	6·0	6·5	5·5	5·8	6·0
Fluavil ..	2·0	3·0	3·0	2·5	2·5

Commercial gutta gives 1·26 per cent. of residue when incinerated, gutta bassia 1·20 per cent. Gutta bassia can be worked into any required shape when softened in warm water, and may be used with advantage for galvanoplastic purposes. —D. B.

Solubility of Caoutchouc. Hanausek. Zeits. Oesterr. Apoth. Ver. 23, 486.

THE statements as to the solubility of caoutchouc in different solvents varying considerably, the author made a number of trials, the following ratios of solubility being obtained:—

	Ceara.	Negro-head.	Sierra Leone.
100 parts of ethyl ether dissolve ..	2·6	3·6	4·5
100 " oil of turpentine dissolve ..	4·5	5·0	4·6
100 " chloroform ..	3·0	3·7	3·0
100 " petroleum naphtha ..	1·5	4·5	4·0
100 " benzene ..	4·4	5·0	4·7
100 " carbon bisulphide ..	0·1	—	—

Oil of turpentine and benzene appear to be the best solvents. —D. B.

The Action of Resins with Reagents. E. Hirschsohn. Pharm. Ztschr. Russl. 1885, 24, 529.

FROM the experiments of the author the following results have been obtained. Alcohol dissolves completely resin from "pinus silvestris" and "picea excelsa;" on the other hand, ether and chloroform dissolve only the former completely, the latter remaining partly undissolved. The same difference in solubility occurs with NH_4Cl and Na_2CO_3 solutions. —J. B. C.

XIV.—AGRICULTURE, MANURES, Etc.

Application of Alkali Waste to the Treatment of Parasitic Diseases. Duponchel. *Compt. Rend.* **101**, 898.

THE solution obtained by digesting alkali waste possesses in a high degree those therapeutic qualities which are found in natural sulphur waters, and can be used either alone or to increase the action of the latter. On account of its extremely low price it may be used for the parasitic diseases of plants, and promises to give excellent results in the case of the phylloxera. For the vine diseases produced by blight the author finds that a single application of this solution is much more efficacious than repeated doses of sulphur as applied in the usual way.

—J. H. H.

On the Treatment of Mildew with Copper Sulphate. A. Muntz. *Compt. Rend.* **101**, 895.

IN order to check the mildew which has of late years been a cause of much damage to some of the vineyards in France, the author has employed solutions of copper sulphate with much success. The vines treated in July with this solution retained their leaves, those not treated lost them. The grapes were enabled after this treatment to ripen completely, whilst those of vines not so treated, failed to do so. The following table clearly shows the difference :—

	Fruit on the Vines not treated.	Fruit on the Vines treated.
Mean weight	1.04grm.	1.45grm.
Sugar in 100grms. Must ..	9.10 ..	15.30 ..
Acids in 1 litre Must (calculated as H_2SO_4) ..	9.60 ..	5.20 ..

The vines were sprinkled by means of a small syringe with 25cc. of a 10 per cent. solution of $CuSO_4$. A 20 per cent. solution seems to give almost as good results, and no trace of copper is found in the wine made from these grapes. A mixture of lime and $CuSO_4$ seems to give still better results.—J. H. H.

On the Effect of a Mixture of Copper Sulphate and Lime upon Mildew in Vines. Millardet and Gayon. *Compt. Rend.* **101**, 924.

THESE authors have also observed the very excellent results of a mixture of lime and copper sulphate as a remedy against mildew in vines. The copper is deposited on the leaves as oxyhydrate, which is only soluble very gradually in water containing ammonium carbonate or carbonic acid in solution. The lime appears to have a three-fold action. In the first place it serves to retain the copper upon the leaves; then it effects the destruction of the spores for several days after its application, in consequence of its basic properties; and, finally, it transforms the copper hydrate into carbonate.—J. H. H.

Estimation of Copper in Vines which had been treated with a Mixture of Lime and Copper Sulphate, and in the Wine, etc., made from them. Millardet and Gayon. *Compt. Rend.* **101**, 985.

THE estimations were made at the time of the vintage. The undried leaves of four different kinds of vines contained respectively 0.0191, 0.0696, 0.0955, 0.0249grm. Cu per kilo. of the leaves. In the stalks of two kinds were found respectively 0.0151 and 0.0186grm. Cu per kilo. In the skins and stones of two kinds 0.0111 and 0.0219grm. Cu per kilo. were found respectively. Four must (vats) contained per litre 0.0014, 0.0012, 0.001, 0.0022grm. Cu. The wines themselves contained only the minutest and indeed doubtful traces of copper, at the most 0.1grm. per 1000 litres, for it is precipitated and found again in the yeast and sediment. Tannin and sulphur added before the fermentation of the must assist in this separation.—J. H. H.

Discovery of Phosphorite Deposits in the South of Tunis. P. Thomas. *Compt. Rend.* **101**, 1184.

THESE deposits were found by the author in the lower tertiary strata extending over a considerable area. The

phosphorites occur in the form of cylindrical coprolites, varying in dimensions, and of yellow clusters, weighing several kilos. The coprolite masses contain 70.8 per cent. of calcium phosphate, the yellow clusters 52.1 per cent., and the small clusters accompanying the latter only 3.34 per cent.—D. B.

Treatment of Lupines. T. Bente. *Pharm. Zeit. Handelsb.* 1885, **30**, 47.

THE author recommends the following process for freeing lupines from their bitter taste. Fifty kilos. of yellow lupines are first treated with a large quantity of spring water, so that, after soaking, they are still completely covered with water; one kilo. of hydrochloric acid free from arsenic is then added, and the mass is allowed to remain for twenty-four hours. One kilo. of a saturated aqueous solution of acid sulphate of calcium is now put into the vessel, the contents of which are stirred and then left for a further period of twenty-four hours. Finally, the fluid is drawn off, and the lupines are thoroughly well washed.

—E. G. C.

Nitrogenous Constituents of the Soil. G. Loges. *Landw. Vers. Stat.* 1885, **32**, 158.

By evaporation of an HCl extract of the soil the author obtained a nitrogenous residue. It may be possible in this way by extracting with HCl to separate humine from nitrogenous humus bodies.—J. B. C.

The Behaviour of Starch and Sugar in Tobacco Leaves. H. Müller-Thurgau. *Landw. Jahrb.* 1885, **14**, 485.

FERMENTED crude tobaccos do not contain, as a rule, starch or sugar, or only small quantities. The quantity of starch in fermented tobacco is, however, no criterion of its quality. Tobacco leaves dried quickly in the sun always contain starch. During the ripening process the under leaves contain less starch than the upper ones, because they are shaded, and attain a greater degree of over-ripeness than the upper ones. The quantity of sugar contained in the fresh, ripe leaves is comparatively small. It increases by drying on the first day, and then diminishes with time. Quickly dried leaves contain a smaller quantity of sugar than those more slowly desiccated. After drying, the sugar present disappears completely during the process of fermentation. The starch, however, does not appear to be influenced.—J. B. C.

XV.—SUGAR, GUMS, STARCHES, Etc.

On the Sources from which Melitose (Raffinose) is obtained in the Manufacture of Sugar. E. O. v. Lippmann. *Ber.* **18**, 3087.

THE author proves that melitose exists already in the beet. This explains both the abnormally high polarisation equivalent and the difference which has been observed between the results of an optical and chemical examination of the beet-juice. (This Journal, iv. 505 and 607.)—J. H. H.

The Clarification of Sugar Solutions. *Sucrerie Indigène*, 1885, **26**, 295.

SODIUM THIOSULPHATE has the property of clarifying those syrups which still remain muddy and dark-coloured, even after the addition of lead acetate.—J. B. C.

Alcoholic Extraction of Beet-sugar. *Ztschr. f. Zucker. Ind.* 1885, **35**, 806.

SUCHOMEL has found, after many years' experience, that Scheibler's data are fully reliable—namely, two hours suffice for extraction, and four hours with very woody beets. A quantity of 40—50grms. of mash gave the same result as the full sample of 3—4kilos., if the preparation and mixing had been carefully done. By dry-

ing and weighing the extract residue, the author determined the crude marc, and found 4–5 per cent. Old beets gave 7.09 per cent.; very woody beets 7.07 per cent. of residue. The statement, therefore, that such beets only contain 80 per cent. of syrup, and therefore 20 per cent. of residue, is quite misleading. Lixivated beet cuttings give twice as much sugar on extraction as by the usual method of pressing, and these results agree with those obtained by Stammer's excellent method.

—J. B. C.

Notes on the Analysis of Finished and Intermediary Products of Sugar Works. L. Harperuth. Chem. Zeit. 9, 1711; and 10, 51.

THE author intends to deal, in a series of articles, with the mode of controlling the operations performed in beet-root sugar works, and his experience of many years leads him to the conclusion that it is absolutely necessary to test regularly the composition of the finished and intermediate products. The analysis of a raw sugar, for instance, ought to contain—1, total dry matter; 2, sugar; 3, non-sugar (invert-sugar and raffinose); 4, factor of purity; 5, ash; 6, refining value ("rendement"). In the beet-root department the control ought to relate to—1, beet-root; 2, washed and cleaned beet-root slices; 3, spent slices as they leave the dials; 4, raw juice; 5, thin juice, unfiltered and filtered; 6, filter-press cake; 7, syrup, unfiltered and filtered; 8, fill-mass of first quality; 9, raw sugar of first quality and the syrups, fill-masses, sugar and molasses of inferior quality. His apparatus for submitting sugar-juice to the action of animal charcoal under variable circumstances is represented in Figs. 1 and 2. A glass cylinder (Fig. 1) has

FIG. 1.

FIG. 2.

two overflows, *a* and *b*; *a* for the discharge of the filtered solution, *b* for running off the liquid completely. The solution enters through the funnel *c* at the bottom, and after passing through the whole length of charcoal, overflows at *a*. If it be desired to treat the juice with charcoal at a constant heat, the apparatus shown in Fig. 2 is employed, where *A* is a glass cylinder filled with animal charcoal, and *B* an iron water-bath, which communicates heat to *A*. The arrangement of the other parts will easily be seen from the diagram. The author's many experiments show that, for an exact analysis, the decolourisation of sugar solutions with animal charcoal involves error; even for technical analysis an addition of tannin is absolutely necessary.—S. H.

Oxidation of Levulose. E. Börmstein and A. Herzfeld. Ber. 18, 3353–3357.

THE authors mention the work which has been done on the subject, and point out that Habermann and Honig

(*Monats. Chem.* 3, 651) found an acid of higher molecular weight than glycollic acid, the constitution of which they were unable to determine. In order to prevent the oxidation products being themselves decomposed by the use of too strong an oxidising agent, the authors used for their experiments a mixture of mercuric oxide and baryta-water. They proceeded as follows:—An aqueous solution of levulose syrup, prepared from inulin, was heated on a water-bath with mercuric oxide, and a small quantity of pure barium hydrate solution added; the red mercuric oxide is immediately reduced to black mercurous oxide. The addition of these two substances was continued in small quantities until a portion of the liquid, after removal of the barium with sulphuric acid, gave no reduction with Fehling's solution. About ten to twelve times as much mercuric oxide as barium hydrate is required for the reaction. The liquid was then filtered from the insoluble mercurous oxide, etc., the excess of barium hydrate removed with carbonic anhydride, the liquid evaporated, filtered, and sulphuric acid added to exact precipitation of the barium present, and the acid liquid distilled with frequent addition of water until all volatile acid had come over. The volatile acid consisted entirely of *formic acid*. The residue was then shaken with ether. The calcium salt of the acid soluble in ether gave numbers on analysis, proving it to be *glycollic acid*. The greater part of the oxidation product remains in the residue, and is not soluble in ether. The calcium salt of the acid remaining in solution forms a yellow syrup, which does not become solid when exposed over sulphuric acid in vacuo, but which can be obtained as a white crystalline powder on repeated treatment of the syrup with strong alcohol. On analysis, this salt gave numbers corresponding to the calcium salt of a *trihydroxybutyric acid*. The free acid forms a thick syrup, which, on reduction with hydriodic acid and amorphous phosphorus, yielded, in addition to an undetermined volatile acid, a lactone; the acid, therefore, is probably *normal trihydroxybutyric acid*. The authors conclude that the constitution of levulose is probably expressed by the formula $\text{C}_6\text{H}_{10}\text{O}_7 \cdot \text{CO} \cdot \text{CHOH} \cdot \text{CHOH} \cdot \text{CHOH} \cdot \text{CH}_2\text{OH}$. They promise further work upon the subject, and also announce their intention of studying the action of bromine on an aqueous solution of levulose.

—G. H. M.

XVI.—BREWING, WINES, SPIRITS, Etc.

On Aspergillus Oryzae. Bot. Centr. 24, 62.

FOR the preparation of "saké" the Japanese use the above-named fungus. Rice is treated with tane-koji, a greenish powder consisting of the spores of the fungus. As soon as the grains of rice have developed mycelium the grain is kneaded together and dried in the air. The resulting product, called "koji," is treated with four volumes of steamed rice. "Koji" contains a powerful substance, acting like diastase, and capable of producing a large amount of dextrose and soluble albumenoids. It begins to act at 0°, gives the most favourable results at 50°, and is destroyed at 60–70°. After the fifth day fermentation sets in and a mass results which is called "moto." This is worked up in conjunction with steamed rice and "koji" in the regular process for the brewing of "saké."—D. B.

The Application and Use of an Improved Salt in Brewing. A. Boake and F. G. A. Roberts, Stratford. Eng. Pat. 5883, May 13, 1885. 4d.

IN this patent the use of "potassium anhydrometa-," or "iso-bisulphite" (Eng. Pat. 5882, 1885), is claimed in any stage of the process of brewing, either to the materials before mashing or to the wort before or after fermentation, and also to the finished beer in casks. The quantity to be used is three ounces to every quarter of malt, or its equivalent in malt substitutes, employed.

—G. H. M.

On Wines manufactured from Dried Grapes, etc. F. Schaller. Zeits. Anal. Chem. 24, 559.

IN spite of the steady increase in the number of artificial wine manufactories in France, Switzerland, and else-

where, there are few published analyses of the manufactured wines, and still fewer sources of information as to the points of difference between these products and natural wines. Besides raisins and emments, sugar, tartaric acid, and many other substances are used in the manufacture of artificial wines, into the composition of some of which the dried grapes have entered to but a small extent. The author gives the following results of the analyses of a few samples of manufactured wines:—

No. 6 was mixed with about 10 per cent of a plastered Spanish wine.—E. G. C.

possible to attain by artificial means; the dough expands in the oven, becomes hard, and loses water. The whole loss is limited to the crust, as the crumb does not contain less water than the dough. Under the influence of heat the proportion of sugar is increased and the fatty substance is diminished. The crust contains more sugar and less fat than the crumb. The expansion of the bread is produced by steam and carbonic acid formed in its preparation. As soon as the bread is taken out of the

oven steam condenses, and the air then entering drives out moisture.—J. B. C.

XVII.—CHEMISTRY OF FOODS, SANITARY CHEMISTRY, DISINFECTANTS, Etc.

(A) CHEMISTRY OF FOODS.

Importance of Edible Fungi as Human Food. R. H. Saltet. Arch. Hygiene, 3, 443.

THE author corroborates the well-known fact of the richness in nitrogenous constituents of edible fungi. He has found 6.8 per cent. of nitrogen in the dried substances of French preserved mushrooms (*champignons*). Contrary to the prevailing opinion as to the digestibility of edible fungi, it is shown that only 75 per cent. of the dried substance is digested; so that edible fungi should not be grouped with animal food, as is frequently done.

—D. B.

Preparation of Bread. Balland. Journ. Pharm. Chim. 1885, 5, ser. 12, 103, 202, 255, 299.

THE results of the following investigations of the author are as follows:—The fermentation of the bread is produced by the natural ferment of the corn, and the process during the preparation of bread is attributed to the action of heat and water in producing activity of the ferment. At first, the glutinous matter becomes hydrated and thin, whereby the necessary firmness is given to the dough, which the starch alone cannot produce. The altered gluten forms, at the same time, a movable network, in which the gases formed are retained. It also gives the bread, when brought into the oven, its particular form. One of the most important points in the preparation of bread is to know the moment in which the gluten possesses its maximum of cohesion. If the action goes on too far the gluten becomes liquid, and does not retain the gases. These escape, and the bread becomes sad. At the same time as the gluten becomes hydrated the starch undergoes the same process, and under the influence of these changes the formation of acid and sugar appear, which do not pre-exist in the cereal. Among the products of decomposition of the sugar, carbonic acid and alcohol are found. All these changes are completed with yeast under the influence of the natural ferment with a regularity which it is not

The Presence of Alkaloids in Old Flour. Balland. Journ. Pharm. Chim. 1885, 5, ser. 12, 341.

FLOUR kept for years in sacks contains alkaloids. The flour is extracted with ether, evaporated on the water-bath, and the strongly-smelling residue taken up with a small quantity of warm water. After again warming for a few minutes on the water-bath, the presence of alkaloids may be detected by reagents, such as potassium, mercuric iodide, ferrieyanide of potassium, and ferric chloride. The alkaloids may be detected one to one and a-half years after grinding the flour. The author ascribes the formation to the action of a ferment upon the glutinous matter of the flour.—J. B. C.

(B) SANITARY CHEMISTRY.

Improvements in the Treatment of Sewage, etc. J. W. Slater, London. Eng. Pat. 4532, April 13, 1885. 6d.

THE essential feature of this invention is the employment, for the treatment of sewage or polluted water, of a water naturally impregnated with alumina. The patentee makes six claims, in which, in addition to the use of the water alone or in conjunction with a water naturally impregnated with iron, salts of alumina, iron, carbon, blood, clay, and any soluble salt of magnesia are severally or collectively used therewith.—C. C. H.

Improvements in the Filtration of Sewage and in Apparatus therefor. C. Price and H. Cleave, Leicesters. Eng. Pat. 2728, February 28, 1885. 8d.

THE sewage is received in a tank containing a cylinder, or tank similar in every respect to the dome of a gasometer. This is filled with air by a force-pump, which causes it to rise, and so exercise a pressure upon the sewage, forcing it (1) upwards through a column of coarse coke; (2) downwards through a column of finer coke; (3) upwards through a column of sand. The solid matter accumulates at the lower part of the chambers, and is removed periodically through openings formed in the walls.—C. C. H.

XVIII.—ELECTRO-CHEMISTRY.

**The Condensation of Dust and Smoke by Electricity.* C. F. Guitard. *Mechanics' Magazine*, October 29, 1850.

"SOME time since, in experimentalising on the electric state of the atmosphere, I employed for that purpose, a large glass cylinder about 18in. high and 9in. diameter, open at bottom and having a neck at top. In placing the lower end of this cylinder in water, the more perfectly to exclude the air, and allowing small quantities of tobacco smoke to enter the neck at top, the smoke, after assuming various actions, according to, probably, the hydrometric state of the atmosphere, would gradually spread itself into a cloud filling the cylinder, and at length, as successive portions came in contact with the sides of the cylinder, condense. Sometimes half-an-hour would elapse before this effect took place. It now struck me that if I brought a wire from an electrifying machine into the neck of the cylinder, the air would immediately become charged with electricity, which would cause each portion of the smoke to fly to the sides of the cylinder, and that thus more rapid condensation would take place. The effect produced was perfectly magical. The slightest turn of a small electrifying machine produced immediate condensation. It was astonishing to see how small a quantity of electricity produced a most powerful effect. I am not aware that attention has ever been drawn to this subject; and the question will probably arise, Has electricity anything to do with the condensation of steam in the condenser?"

The Manufacture of Improved Plastic Compounds. R. E. Goulden, Hanover Square, London. Eng. Pat. 2742, February 28, 1885. 4d.

IMPROVED plastic compounds suitable for insulating material for galvanic batteries, are made by mixing, and combining by heat gum damar, gum kamri, gutta-percha and asbestos or other suitable pigment.—W. B.

Improvements in the Manufacture of Electrical Batteries. L. P. Merriam, Romerton. Eng. Pat. 3888, March 26, 1885. 4d.

IN order to prevent leakage of the solution or liquid in electrical batteries at the joints of a cell or trough, the author proposes to form the joints by means of xylonite or some other pyroxylin compound which is not affected by ordinary battery solutions or liquids.—W. B.

Improvements in the Manufacture of Nickel and Cobalt. H. Wiggin, H. A. Wiggin, A. S. Johnstone, and W. W. Wiggin, Birmingham. Eng. Pat. 3923, March 27, 1885. 6d.

THIS is a process for separating copper from nickel and cobalt, and consists in obtaining the metals in solution, preferably as chlorides, sulphates or nitrates, by well-known methods, and subjecting the solution to the action of an electric current. With a cathode of copper or brass and an anode of compressed carbon, the copper is reduced by the electric current and deposited on the cathode, and the chlorine or acids which were combined with the copper are liberated at the carbon anode.

—W. B.

Improvements in Boxes or Cells for Primary and Secondary Batteries. Charles Mosley, Manchester. Eng. Pat. 4155, April 2, 1885. 4d.

IN a box or cell of a primary or secondary battery is secured a lining of indiarubber; or an indiarubber com-

pound is cemented therein. To prevent the creeping of the solution over the top edge of the box or cell, the upper edges of the lining are coated with paraffin or some such analogous substance.—W. B.

Improvements in and connected with Galvanising Baths. Thomas Minnis, Wolverhampton; and E. Ingram, Birmingham. Eng. Pat. 4584, April 14, 1885. 6d.

By this method three adjustable rollers are used in a galvanising bath, whereby a saving of flux is effected on the delivery side of the bath.—W. B.

Improvements in Voltaic Batteries. A. R. Bennett, Glasgow. Eng. Pat. 5256, April 28, 1885. 4d.

WITH the object of increasing the constancy of the current produced by the various forms of voltaic batteries described and claimed in the specifications of the author's patents Nos. 302 of 1882, and 1901 of 1882, he employs, in conjunction with the chemicals therein set forth, metallic sulphides, more particularly the various sulphides of iron and copper, and the joint sulphides of iron and copper.—W. B.

Improvements in Galvanic Batteries and in the Electrodes of Electrolytic Converting Tanks or Troughs. W. H. Tasker, Bedford Square; and T. J. Jones, Princes Street. Eng. Pat. 8627, July 16, 1885. 8d.

THIS invention relates to the construction of elements for galvanic batteries, particularly the negative elements of lead primary batteries, and it has for its principal object to provide a support for the active material. The support consists of an inoxidisable substance, of any desired form, which is slit for the passage of strips of foil, the said strips being laced or passed through the slits to and fro from side to side so as to afford good contact with the active material on both sides of the support, and practically utilise the whole or greater part of the external surface of the foil for this purpose.

—W. B.

Improvements in the Production of a Carbonisable Material suitable for the Manufacture of Carbons for Electric Lamps, etc. F. Wynne, Westminster; and L. S. Powell, Notting Hill. Eng. Pat. 16,805, December 22, 1885. 6d.

A TRANSPARENT horny substance, suitable for electric lamps, is produced by dissolving cellulose in the form of cotton or other vegetable fibre or fabric in solutions of the chlorides, iodides or bromides of zinc or bismuth, and precipitating by alcohol, ether, acetic acid, etc.—W. B.

XIX.—PAPER, PASTEBOARD, Etc.

Machinery or Apparatus for Separating, Washing, and Drying Fibre from Peat. F. Baird, London. Eng. Pat. 860, October 16, 1885. 8d.

THE separating and washing is effected by the use of a series of drums placed in a tank of water. The material, fed through a hopper, passes between two plain drums (which simply reduce its thickness) on to an endless chain, which carries it to another pair of drums. These are provided with teeth, which manipulate the peat into fine fibre and throw it into a washing-tank, whence it is conveyed to a strainer and afterwards to a drying-room.

—A. R. D.

XX.—FINE CHEMICALS, ALKALOIDS, ESSENCES, AND EXTRACTS.

Action of Light on Iodoform. G. Dacombe. *Ann. di Chim.* 1885, 209.

THE decomposition of iodoform in sunlight with separation of iodine is effected only in the presence of oxygen, in which case the reaction is complete. The following equation expresses the change which occurs:— $2\text{CHI}_3 + 5\text{O} = 3\text{I}_2 + 2\text{CO}_2 + \text{H}_2\text{O}$.—D. B.

* Mr. W. M. Hutchings, of the Dee Bank Lead Works, Bagilt, North Wales, forwarded the above verbatim extract, and desires moreover to draw attention to *Berg. und Hütten-männische Zeit.* June 19 and July 10, as also to *Engineering*, June 5, 1885, where articles on the above subject occur. In view of recent investigations of this subject, it was thought interesting to reproduce here what was probably the first observation of these electrical phenomena.

Green Colour imparted to Dilute Solutions of Apomorphine Hydrochloride. Bernbeck. Pharm. Zeit. **30**, 874.

WEAK solutions of apomorphine hydrochloride gradually undergo decomposition with formation of an emerald-green colouration. This change is attributed by the author to the presence of ammonium carbonate in the water used for dissolving the hydrochloride, or in the atmosphere, especially the air of sick-rooms. A small amount of hydrochloric acid prevents the formation of this colouration.—D. B.

Green Colouration exhibited by Apomorphine Solutions. E. Mylius. Pharm. Zeit. **30**, 883.

THE green colouration assumed by apomorphine solutions is attributed, not only to the action of ammonia, but to that of the fixed alkalis.—D. B.

Comparison of the Ethereal Oils of Mentha Piperita and Mentha Viridis. H. Trimble. Amer. Apoth. Zeit. **6**, 492.

BOTH oils contain the same hydrocarbon, $C_{10}H_{18}$. The latter is present, however, in smaller quantity than hitherto assumed, and cannot be isolated without difficulty. The oxidised constituent in the oil of *mentha viridis* is carvol $C_{10}H_{12}O$, that of the oil of *mentha piperita*, pimenthol $C_{10}H_{20}O$, a body which is solid and crystalline at the ordinary temperature.—D. B.

African Cinchona Bark (so called). E. Heckel and Schlagdenhaufen. Ann. Chem. Phys. **6**, 313.

BOCHEFONTAINE, FERIS, and MARCUS have found an alkaloid called "Doundakine" in African cinchona bark. The authors, on examining this bark, obtained the following results:—

Soluble in petroleum spirit: Wax, fatty bodies	1.200%
" " chloroform: Wax, fatty bodies, and colouring matters	1.040
" " alcohol: Traces of tannin, glucose, and resinous colouring matters	6.950
" " acidulated water: Albumenoids and amylaceous substances, salts	23.112
Woody fibre	62.128
Salts	5.570

100.000

They deny the existence of the above alkaloid. The physiological action of the bark is due to the presence of a colouring matter, for which the authors propose to adopt the name "Doundakine." The bitter taste of African cinchona bark is caused by two nitrogenous colouring matters of resinous consistence, distinguished by their different solubilities in water and alcohol. African bark possesses tonic and febrifuge properties.—D. B.

New Nitrogenous Constituent of Vetches, etc. E. Schulze and E. Bosshard. Zeit. Physiol. Chem. **10**, 80.

THIS substance, called *Vernine*, was prepared as follows: Young leaves of the common vetch (*Vicia sativa*) and the red clover (*Trifolium pratense*) were dried, ground, and exhausted with hot water. The extract was treated with lead acetate and mercuric nitrate, and the resulting precipitate decomposed by hydrogen sulphide. The filtrate was neutralised with ammonia and concentrated by evaporation. Besides crystals of asparagine an amorphous precipitate was separated which, when recrystallised from hot water, gave shining needles of vernine, having the composition $C_{16}H_{26}N_4O_8$. Vernine has been extracted also by the authors, in conjunction with Hungerbühler, from blighted corn, 1 kilo. of substance yielding about 1 gram. of vernine.—D. B.

Hopine, the Alkaloid of Hops. Dr. W. Williamson. Chem. Zeit. **10**, 20, 38.

SEVERAL writers have supposed that the hop contained an alkaloid, and Griessmeyer described a crystallisable compound containing nitrogen, which gave a number of

the reactions peculiar to vegetable alkaloids. Still, as no one had obtained it in sufficient quantity for analysis, the author undertook an investigation of this most important constituent of the hop, and at last obtained the pure alkaloid from the American wild hop. The German and English hops contain very little hopeine, and its separation from the colouring matter of the plant offers in their case insuperable difficulties, though doubtless some is present. A wort of twelve per cent. strength was first made from as many hops as the brewing pan would hold; this was then boiled down at $45^{\circ}C$. in a vacuum pan of 10,000 litre capacity to a thick syrup. This product, in the case of the American wild hop (*Humulus Lupulus L.*), had a powerful narcotic effect, weaker in the case of English hops and weakest of all with German hops. The extraction of the pure alkaloid from this solution cannot, however, be effected, but by heating with alcohol an extract is obtained which is not inferior to opium in narcotic properties, and has an intensely bitter taste. A few grains of this alcoholic extract killed dogs and rabbits in less than two hours. As, however, it was not possible to obtain the pure alkaloid by a direct extraction of the hop or *Lupulus* with alcohol, a twelve to sixteen per cent. slightly acid sugar solution was poured upon the hops contained in large copper hermetically closed boilers. The sugar solution was as pure as possible, heated to $60^{\circ}C$. before addition to the hops, left with them for 24–48 hours, then boiled about six hours and quite cooled, and the hops separated from the liquid by a centrifugal machine. The sugar extract was then filtered, evaporated as far as possible in a vacuum in order to avoid the formation of caramel, as this body, if formed, makes the isolation of the alkaloid almost impossible. The evaporation was continued until upon cooling a solid mass of sugar was obtained, which upon pulverising formed a tolerably dry powder. This powder, which is coloured yellow by the hops and an extract with alcohol, leaves upon evaporation to dryness a clear brown residue which possesses all the properties of a narcotic alkaloid. This residue was again extracted with alcohol, and by successive treatment with weak ammonia water, ether, chloroform and benzene, the impurities were eliminated and the pure hopeine obtained by repeated crystallisation. Hopeine appears most nearly to resemble morphia, from which, however, it can easily be distinguished both by taste and by several characteristic reactions. In the pure state hopeine forms colourless prismatic needles or rhomboids, according as the mother-liquor contains more or less alcohol. The crystals must be dried in vacuo, or they assume a yellowish tint. Its formula when crystallised from 80 per cent. alcohol is always $C_{18}H_{26}NO_4 + H_2O$; when crystallised from 20 per cent. alcohol it always contains two molecules of water of crystallisation. The powder dried at $80^{\circ}C$. always has the composition $C_{18}H_{26}NO_4 + H_2O$. Upon heating to $110^{\circ}C$. in the air, or $75^{\circ}C$. in vacuo, all the H_2O evaporates, and at a higher temperature in the air decomposition takes place, whilst in vacuo it volatilises undecomposed.

The salts are mostly soluble in water and crystalline; pure hopeine is only soluble in 800 parts of water at $15^{\circ}C$. or about 50 of alcohol; in ammonia and ether dissolve about 0.1 per cent., chloroform not more than 0.2 per cent. Heated to 80° or $90^{\circ}C$. with a little alcohol, discolouration and partial decomposition set in.

Hopeine Sulphate $2(C_{18}H_{26}NO_4) \cdot H_2SO_4 + 4H_2O$.—Very easily soluble in water; crystallises from aqueous alcohol in forms very similar to the pure hopeine. *Hopeine Hydrochloride* is less soluble in water than the sulphate, and like all the haloid compounds is stable in the air; it crystallises with three molecules of water. The *Iodide* and *Fluoride* are similar, but still less soluble. The *Acetate* $C_{18}H_{26}NO_4 \cdot C_2H_3O_2 + H_2O$ is easily soluble in water and decomposes readily in air. In many of the salts the water of crystallisation varies according to their mode of preparation, as, for instance, the *Tartrate*, which may contain three, four, or five molecules of water. The *Salicylate* is easily crystallisable, fairly soluble, and very stable. The author states that the

very small yield of hopeine from a large quantity of hops, and the difficulty of treating such a large bulk of material, have induced him to continue his research with the so-called lupuline or hop-meal, from which he hopes for better results. 0.15–0.22grm. of the hopeine kill most animals. Smith and Roberts have shown that injected subcutaneously its action exceeds that of morphia, and internally applied it is certainly not less potent. It is also an antiseptic of the first rank, more powerful than any of the other alkaloids. These results correspond with the action of hops, which are known to retard fermentation and putrefaction in the highest degree.—J. H. H.

On Hopeine. A. Ladenburg. Chem. Zeit., 10, 319.

HAVING obtained, through Dr. Krause, a small quantity (0.47grm.) of the hopeine prepared by Dr. Williamson himself, the author states that he succeeded in separating the so-called hopeine into two bodies, the one with difficulty soluble, the other much more easily soluble in amyl alcohol. The properties of the former are identical with those of morphia, but the latter is a base requiring further investigation. This more soluble base yields no colour reactions either with ferric chloride or with sodium molybdate and sulphuric acid. It is not soluble in excess of soda, but is tolerably easily soluble in ether containing water.—W. S.

Examination of Oil of Mint for Turpentine. H. Hager. Pharm. C.-H. N. F. 1885, 589.

THE author is of opinion that turpentine is rarely mixed directly with the oil of mint, but that it is poured upon the mint when in the retorts, and that much of it remains behind there. The oil thus incorporated with turpentine differs materially in physical and chemical properties from that merely mixed with distilled turpentine. But the presence of turpentine is shown at once by employing the following method: 0.15grm. powdered guaiacum resin are placed in a dry test tube, and fifteen to twenty drops of alcohol added; the mixture is then heated to boiling, 1cc. of oil of mint, 1cc. of benzene or petroleum spirit, and five to six of oil of citrocelle added, and the mixture gently agitated and heated for some time to boiling. This solution, with the pure oil, has a brownish yellow tint, but if turpentine be present a violet colour is produced.—J. H. H.

Contributions to the Knowledge of Cocaine. E. Polenske. Pharm. Rundsch. 3, 250.

THE amount of alkaloid in coca leaves varies from 0.05 to 0.75 per cent., and depends on the method of drying adopted, the mode of packing and shipping. According to the author, coca leaves contain only one alkaloid, all other organic bases observed in the leaves being decomposition products of cocaine. Besides its physiological properties, cocaine may be distinguished by its slight solubility in water (1:2500 at 15°). When dilute solutions of the hydrochloride are treated with ammonia and carbonated alkalis, the liquid assumes a milky turbidity, solidifying after a while to a crystalline mass. Cocaine hydrochloride crystallises from water in long silky needles, containing two molecules of water.—D. B.

On the Detection of Cocaine. Prof. Curtman. Pharm. Rundsch. 1885, 252.

COCAINE is a strong reducing agent. The author mixed a freshly prepared solution of pure ferrieyanide of potassium with ferric chloride, and shaded the mixture from the light. He moistened filter paper with this solution, and then applied in a darkened room equivalent portions of solutions of the alkaloids. Morphia gave the blue reaction in less than half-a-minute; cocaine, in 1½ minutes; brucine, in 6; quinine, in 7; cinchonine, in 10; while strychnine and veratrine gave no trace of blue after standing a quarter-of-an-hour.

Of the other tests, the most reliable seems to be that based upon the formation of benzoic acid upon warming with weak acids. The benzoic acid can afterwards be detected in the usual manner.—J. H. H.

The Decomposition of Oil of Turpentine into an Active Terpene. G. Bonchardat and J. Lafont. Compt. Rend. 1886, 102, 50.

1200GRMS. of oil of turpentine carefully fractionated between 155–157° were dissolved in an equal volume of glacialacetic acid and treated with an acetic acid solution of 880grms. crystallised chromic acid, the latter being slowly added to the solution of the oil maintained below a temperature of 40°. No CO₂ escaped, and, although the larger portion of the oil was not oxidised, it nevertheless underwent a distinct change. A product, having the formula C₁₀H₁₆, and boiling at 174–178°, which the authors call levorotatory terpene, was isolated. Its properties are entirely different from those of turpentine oil. Its smell recalls that of oil of lemons. This terpene contains about one-sixth its weight of cymene, from which it could not be separated. Its rotatory power was found to be (α)_D = -56°, that of citrene being +104.9°. The chemical properties of the two bodies are identical.—J. B. C.

The Alkaloids of Aconitum Napellus. Alexander Jürgens. Inauguraldissert. Dorpat, 1885.

THE following are the results of the author's studies on this much-discussed subject:—(I.) Only pure crystallised aconitine should be used as a pharmaceutical preparation. (II.) The occurrence of picro-aconitine, napelline, and aconelline in the roots of the acon. nap. has not been proved. (III.) The presence of aconitine in forensic chemistry can only be detected with the help of physiological experiments. The formula for pure aconitine is C₃₄H₄₈NO₁₂. The colour reactions with phosphoric acid, sulphuric acid and sugar, phospho-molybdic acid and ammonia, affirmed by different authors, are not produced by the pure compound.—J. B. C.

The Detection of Gamboge. E. Hirschsohn. Pharm. Ztschr. Russl. 1885, 24, 609.

GAMBOGE dissolves in petroleum spirit with an intense yellow colour. This solution is decolourised on shaking with solutions of NH₄Cl, NaOH, borax, and Na₂CO₃, the resin being extracted from the petroleum. If to the petroleum extract of gamboge a few drops of an alcoholic ferric chloride solution be added, the alcohol at the bottom of the test-glass is coloured intensely black. If two to four volumes of a solution of ammonia in petroleum be added, the resin is precipitated, and is no longer soluble in petroleum spirit. The author has devised from these reactions the following method for detecting gamboge:—The sample is finely powdered, and treated with petroleum spirit. If the extract be colourless, the shaking must be repeated, with the addition of HCl, as in presence of soap the gamboge is not dissolved. If the extract still remains colourless, gamboge is not present. If a yellow solution is obtained, a portion is shaken with dilute NaOH (1:100); and if a red colouration occurs from the presence of rhabarber and radix. lapat. it is saturated with ammonia gas, and the precipitated resin separated. The precipitate dissolved in alcohol should turn black with Fe₂Cl₆.—J. B. C.

On the Sulphonic Acids of Strychnine. C. Stoehr. Ber. 18, 3429–3432.

CRYSTALLISED strychnine, melting-point 265–266°, when heated with the necessary quantity of concentrated sulphuric acid at 100°, forms a monosulphonic acid, with a nearly quantitative yield. According to Loebisch and Schoop, under these conditions strychnine is not attacked. This monosulphonic acid, C₂₂H₂₁N₂O₂.SO₃H, is a colourless substance, very little soluble in water or alcohol. The ammonium salt is very soluble in water,

from which alcohol precipitates it; the potassium, sodium, barium, calcium, lead and copper salts form very insoluble precipitates. Concentrated sulphuric acid and sulphuric anhydride at 150° form readily a disulphonic acid, the yield being also good. The free acid, $C_{21}H_{20}N_2O_2(SO_3H)_2$, is a colourless amorphous substance, soluble in water, slightly soluble in alcohol, ether and benzene. Its normal barium salt, $C_{21}H_{20}N_2O_2(SO_3)_2Ba$, forms colourless tables or cubes; the hydrogen-barium salt—

a pale yellow amorphous powder is obtained by adding hydrochloric acid to the solution of the normal salt.

—T. L. B.

XXII.—GENERAL ANALYTICAL CHEMISTRY.

A Vacuum-Desiccator with a Heating Arrangement.

J. Prakt. Chem. 9, 425.

THE arrangement consists either of a steam-coil (Fig. 1) into which a metal basin is placed serving as a sand-bath, or of a jacketted copper dish (Fig. 2) which heats

FIG. 1.

FIG. 2.

the sand by means of steam. For the purpose of boiling down large quantities of liquid in a vacuum, the solution is run into the evaporating basin either from a funnel at the top (Fig. 1) or is sucked from a beaker as shown in Fig. 2. The connection with the air-pump is at the bottom at *m*. When all is evaporated a slow current of dried air is passed over the dish, which promotes the drying considerably.—S. H.

Improvement in the Soxhlet Extraction Apparatus.

Chem. Zeit. 10, 52.

THERE is a disadvantage in connection with the Soxhlet apparatus that the siphon tube through which the ether flows back into the flask has an unalterable length. The mass to be extracted may take up more or less space, and in the latter case the amount of ether lying above the mass takes no part in the extracting process. To remedy this drawback it is suggested to use hollow glass cylinders, having a conical top and a small hook, to withdraw them readily if not wanted. They are a little thinner than the body of the apparatus, and high enough

just to reach to the overflow of the siphon tube. They are also loaded with a drop of mercury to prevent them from floating.—S. H.

A Non-metallic Gas-regulator. II. Schidl. Ber. 18, 2833–2841.

THE form of the apparatus is given in the diagram, Fig. 1.

A tube A, closed at its lower end, stands upon a wooden foot, which also supports the whole apparatus. Two side pieces of tubing are fused on to the lower end of the tube A, and an inverted bottle B of capacity $\frac{3}{4}$ –1 litre with the bottom removed fits over the upper portion. The bottle is filled with water. In this a $\frac{1}{2}$ -litre flask C, with neck detached, floats, and surrounds the vertical tube, leaving a space of about 2mm. The flask moves a glass lever D fixed by a cork or caoutchouc plate 3mm. thick into the bulb of the cross piece E. The short arm D within the bulb is flattened, and to its lower surface a small piece of caoutchouc is attached. The plate forms a valve to the tube F, the upper end of which is drawn out so as to form an opening of about 2mm. diameter, and this tube F fits tightly into the lower arm of the cross piece. The gas enters through *b* into the cross piece, forces up the gauge *c* containing coloured water, and passes through the narrowed opening of the

FIG. 1.

tube F, through the tubing G and *d* into A, where it fills the flask C and then by *e* to the burner. H is a brass stand for clamping the cross piece in position. The regulator should be supplied from an ordinary gas tap, and as this will deliver more gas than is utilised, the pinch cork is used to regulate the delivery.

The apparatus is so arranged that at the ordinary daily pressure the valve is $\frac{1}{2}$ mm. distant from the upper opening of the tube F, while the longer arm of the lever just touches the flask. To prevent accumulation of mould in the flask the author adds $\frac{1}{2}$ per cent. of phenol and acidifies the solution.

Fig. 2 represents a regulator devised by Giroud, and found very practical for general purposes. The construction and working of the apparatus may be readily understood from the diagram. When the tap is closed

the apparatus forms an ordinary regulator. For higher temperatures the tap is opened more or less. For lower temperatures the opening in the bell is partly closed

FIG. 2

with stearic acid. It is not advisable to screw a lamp directly on to the regulator, as the latter thereby becomes heated and no longer acts—J. B. C.

Estimation of Phosphoric Acid. J. Laubheimer. Chem. Zeit. 9, 1870.

THIS method, which is simple and rapid in execution, may be employed in all cases where hitherto it has been necessary to use the Molybdic method, the results being as accurate as those obtained with the latter method. For this purpose 25 or 50cc. of the phosphoric acid solution (containing from 0.1 to 0.2 grm. P_2O_5) are treated with 10cc. of citric acid (500 grms. per litre). Ammonia is then added in large excess, and the cold mixture treated with 15 to 20cc. of the usual magnesia mixture. A crystalline precipitate is produced, the separation of which is facilitated by stirring with a glass rod for one or two minutes. After standing all night the precipitate is thrown on a filter, washed with ammoniacal water, and finally with alcohol. It is then ignited in a platinum crucible and weighed. Phosphates rich in iron—e.g., Thomas' slag—require the use of a larger amount of citric acid and ammonia. Fassbender, of the experimental station of Kempen, has estimated the phosphoric acid in a variety of manures by this method, and compared the results with those obtained by the Molybdic method. The figures agree very closely.—D. B.

Notes on the Estimation of Iron and Aluminium in the Presence of Phosphoric Acid. M. Kretschmar. Chem. Zeit. 9, 1905.

THIS paper is a supplement to a former article (*Chem. Zeit.* 9, 942), in which the author described an indirect method for the estimation of iron and aluminium in superphosphates. He now points out that the determination of iron is very important, recent investigations having shown that the "going back" of phosphoric acid is chiefly due to the amount of iron, and less to the percentage of aluminium, in a phosphate. All direct methods for separating iron and aluminium are very tedious operations; the indirect process is more expeditious and very exact. If, however, a direct estimation be desired, it is best to precipitate iron and aluminium phosphate, and after determining their weight, to fuse the precipitate with potassium hydrate in a silver crucible.—S. H.

New Method for the Estimation of Phosphorus in Pig Iron and Steel. W. Kulmann. Monatsh. Chem. 6, 818.

ACCORDING to the quantity of phosphorus present, one to ten grammes of ore are fused cautiously with once or twice their weight of a mixture of two parts of calcined magnesia and one part of $KNaCO_3$ in a platinum crucible over the flame of a Bunsen's burner for one hour, stirring every ten minutes. After cooling, the melt is dissolved, and to its solution whilst being warmed, is gradually added sufficient citric acid to manifest an acid reaction. The liquid is then filtered, and the residue washed first by decantation, then upon the filter, with a one per cent. citric acid solution, until the filtrate with NH_4Cl and NH_4OH does not give any turbidity upon standing. To the filtrate is added NH_4Cl , and then about one-quarter its volume of strong ammonia, in order to precipitate the ammonium magnesium phosphate. When this precipitate has settled, it is filtered carefully and then dissolved in HCl and precipitated again with ammonia. After standing $1\frac{1}{2}$ to 2 hours it is filtered, and then treated in the usual way.—J. H. H.

A Simplification of the Molybdenum Method for the Estimation of Phosphorus. M. A. von Reis. Rep. Anal. Chem. 5, 381.

THE following rapid method gives good results:—Five grms. steel raspings are covered with 80cc. HNO_3 of sp. gr. 1.20. The whole is left thus for half-an-hour at about $100^\circ C.$, the vessel standing on a plate heated with steam. Then mixed with 50cc. of ammonium nitrate solution (seventy-five per cent.) and 10cc. NH_4OH of sp. gr. 0.91, precipitated with 50cc. molybdenum solution; digested and well stirred for one hour at $80-90^\circ C.$ The precipitate is washed with a solution of 150grms. NH_4NO_3 and 50cc. HNO_3 in one litre of water, and then dissolved in concentrated, and washed with dilute ammonia. It is then mixed with 10cc. of a ten per cent. ammonium chloride solution, precipitated with 5cc. magnesia mixture, let stand two hours, filtered, washed with 2–5 per cent. ammonia solution, the filter dried with the precipitate in a porcelain crucible in the air-bath, heated to a clear red heat for twenty minutes in the furnace, and weighed. Instead of this final precipitation with magnesia mixture, the author proposes to reduce the molybdic acid to the brown oxide, M_2O_3 , with zinc and acid, and then to titrate back to the molybdic acid with permanganate, and he gives full details of his process. (*Chem. Zeit.* 9, 852; and this Journal, iv. 179, 524; iii. 141, etc.)—J. H. H.

Detection of Mineral Oil and Resin Oil in Fat Oils. Oleins, etc. Focke. Rep. Anal. Chem. 5, 349.

ABOUT 20grms. of the sample are saponified on the water-bath with 8–10grms. of caustic potash and 50cc. of alcohol; the latter is evaporated, the soap is dissolved in water, the solution precipitated with hydrochloric acid, and allowed to cool when the stratum of separated fatty acids has become clear. The dilute acid solution is poured off, and the fatty acids are washed with water until the washings no longer exhibit an acid reaction. If necessary, the wash-water is filtered from any separated particles of fatty acids. The fatty acids (with any hydrocarbons present) are dissolved in ether, and the filtered solution is evaporated or distilled. The residue is weighed at intervals, the weight being considered constant when, after 15 minutes' drying, the diminution is only in centigrammes. To the solution of about 10grms. of fatty acids in 50cc. of alcohol are added some phenolphthalein, slight excess of caustic soda (1:3), and then, quickly, 100cc. of petroleum ether, which has been freed by distillation from hydrocarbons boiling above 100° . The mixture is now vigorously shaken, allowed to separate, then mixed with 500cc. of water gently turned and shaken, and finally placed on one side (should the alcoholic soap solution be "set" before the addition of the petroleum ether, it must be caused to liquefy by gentle warming). The aqueous soap solution

is poured off, after complete clearing, and the petroleum ether solution is again treated with 300cc. of water. When the greater part of the watery solution has been removed with a syphon, 10cc. of alcohol are added in a thin stream to the incompletely clear ethereal solution. Ten minutes later, the mixture is transferred to a separating funnel. The 80–85cc. of clear petroleum ether solution are evaporated in a large deep watch-glass. The percentage of neutral fats may also be estimated by titrating the fatty acids in the original substance, deducting this result from that obtained by the titration of the separated fatty acids, and dividing the difference by 95, as the oil used by manufacturers for oiling the wool contains on an average 95 per cent. of fat acids.

—E. G. C.

Examination of Commercial Glycerine. H. L. Sulman and E. E. Berry. *Analyst*, 11, 12–15 and 34–38.

THE published figures of the specific gravity of glycerine vary greatly, but are usually between 1.260 and 1.270. The authors have adopted Lenz's figure, 1.2675 at 15° C., as the most accurate, the lower results of other chemists being attributed to the great difficulty in concentrating glycerine completely without decomposing it. The approximate percentage of water in aqueous glycerine may be calculated from the formula—

$$\frac{1267.5 - 1000 D}{2.675 D}$$

where D is the observed specific gravity.

Neither the colour nor the specific gravity of a sample are safe indications as to whether it consists of crude or of distilled glycerine; as a rule, the latter is light in colour and rarely exceeds 1.261 in gravity, whereas the former is usually dark, and its gravity may be as high as 1.360.

To make certain of what the sample consists it must be ignited, as the amount of mineral residue in distilled glycerine is *never* more than 0.2 per cent., whereas *all* samples of crude contain much more, usually 9–14 per cent. in glycerines made from soap leys, though not so much in those from candle factories.

Organic Impurities.—Crude glycerine always contains albuminous matter, and usually resins (if from soap leys); the latter give rise to rosin oil in the distilled glycerine, in which it can be detected by agitating with ether, decanting and evaporating, when the rosin oil can be detected by its characteristic smell and taste. If crude glycerine (from soap leys) be acidified a white precipitate, consisting chiefly of resin and free sulphur, is obtained.

The traces of mineral matter in distilled glycerine may consist of sodium chloride, iron and copper. The chief organic impurities are formic, butyric and oleic acids, rosin oils, colouring and empyreumatic products, and occasionally organic sulphur compounds.

To determine the amount of *total mineral matter*, two portions of the sample must be ignited. As soon as the first has become completely charred it is taken up with water, filtered, and the sodium chloride determined in the filtrate by titration. The second portion is ignited until all the carbonaceous matter has been burnt off; the residue is then weighed, dissolved in water, and the amount of chloride in it ascertained. The difference of the sodium chloride determinations, added to the weight of the second ash, gives the total amount of mineral matter.

Chlorides cannot be determined directly in glycerine, since this dissolves an appreciable amount of silver chloride, and, if impure, reduces silver nitrate.

Crude glycerine usually contains 0.5 to 2 per cent. of alkali, generally as sodium carbonate, which can be determined by titration with standard acid, litmus being the best indicator.

Lime may be detected by adding to the glycerine an equal volume of alcohol containing 1 per cent. of sulphuric acid, or by the ordinary ammonium oxalate test.

The *total Organic Impurities* are determined by a modification of Champion and Pellet's process. The

glycerine is diluted with water, warmed with acetic acid to expel carbonic acid, an excess of basic lead acetate added, and the precipitate filtered off, dried, and weighed. It is then ignited with a little nitric acid, the residue weighed and deducted from the dried precipitate, when the amount of organic impurity is found. The object of the nitric acid is to prevent the reduction of any sulphate present. It is not accurate to ignite the above-dried precipitate with sulphuric acid, multiply the weight obtained by .736 and then deduct this from total weight, assuming the difference to be "organic impurities." In this process the sulphuric acid, of which some is usually present in crude glycerine, would be included in the organic matter. The amount of this latter should not exceed 0.5 to 1 per cent. in distilled glycerine.

Fatty Acids are detected by passing peroxide of nitrogen through the diluted glycerine, when a yellowish flocculent precipitate is thrown down.

Sugar may be detected by Mason's test, using 0.5cc. of the suspected glycerine, 15cc. water, 2 drops strong nitric acid, and 0.5 grammes of ammonium molybdate. On boiling for a short time a blue colouration is produced if 0.25 per cent. of sugar, glucose or dextrin (*not* lactose or arabin) be present. The liquid must not be highly coloured nor very acid.

Quantitative Estimation of Glycerine.—Dr. Flemming neutralises with acid, filters, adds milk of lime, and evaporates to dryness. The residue is completely exhausted with a mixture of alcohol and ether (3:1) and the solution evaporated, dried at 115° and the residue weighed. It is then ignited and the ash deducted from the previous weight. This process is not accurate, on account of the volatility of glycerine during concentration, and figures are quoted from a paper by Nessler and Barth, who conclude that the loss of glycerine depends on (1) the height of the walls of the vessels, (2) the conductivity of the heat of the same, and (3) the area of the exposed surface of the liquids.

Morawski's Method consists in slowly heating the glycerine with lead oxide to 120° to 130° till the weight is constant. A glyceride of lead ($\text{PbO.C}_3\text{H}_5\text{O}_2$) is formed, and the increase in weight of the lead oxide multiplied by the factor 1.2432 gives the percentage of glycerine in the sample. The results are very satisfactory, but the process cannot be used if mineral or organic impurities are present.

Attention is called to two misprints in the abstract of this process in the *Jour. Soc. Chem. Ind.* (vol. i. 75), where *peroxide* of lead is given instead of oxide, and the factor 1.3429 (which is also wrongly given in Morawski's original paper) instead of 1.2432. It was found that the long preliminary desiccation of several hours was not essential, and that a good result could be obtained by merely heating the mixture of lead oxide and glycerine to 120° to 130° C. for two hours, provided the mixture was covered with a thick layer of dry lead oxide.

Dr. Muter's Method (*Analyst*, vi. 41, and Allen's "Org. Commercial Analysis," vol. ii.) is preferred, but it is not available for crude glycerine unless it be previously treated with basic lead acetate (and the excess of lead afterwards precipitated), so as to remove the albuminous matter, which itself dissolves copper oxide in an alkaline solution.

J. Puls's Process is similar to Muter's, and he has shown that in solutions containing 1.85 to 5.80 per cent. of glycerine, 73.5 parts of CuO will always be dissolved by ninety-two parts of glycerine (one molecule) in the presence of ninety-four parts of potash (K_2O); this ratio of glycerine to copper oxide is *not* constant, however, beyond the above limits. Hence, in using Muter's method, the authors prefer to use for the check experiment a solution containing as nearly as possible the same proportion and same actual weight of glycerine as there is in the known volume taken of the filtrate obtained after purifying the crude glycerine sample by basic lead acetate.

Zsigmondy and Benedikt's Process consists in oxidising glycerine to oxalic acid by an alkaline permanganate solution and estimating the oxalate by precipitation

Ferric Oxide.—10grms. are required for 10cc. of wine. Erythrosin, acid magenta, Bordeaux red, and roccellin red, are not acted upon. All other fuchsin colours are extracted. The author considers that upon these preliminary results a general and reliable method may be eventually built up.—J. B. C.

Method for Estimating Tannin. F. Jean. Bull. Soc. Chim. 1885, 44 183.

A CIRCULAR piece of paper .05 in diameter is laid upon a piece of black cloth about 20cm. square, and placed near a well-lighted window. Upon this a beaker is placed of 800cc. cap. and .085 inside diam., a volume of 200cc. being indicated by a mark. 5cc. of Fe_2Cl_6 solution are run into the beaker (the solution contains 14grms. Fe_2Cl_6 and 10cc. HCl in the litre) and to this 1 p.c. solution of tannin is added drop by drop. After each addition the liquid is quickly agitated with a glass rod, and observed as soon as the circular movement begins to cease. The operation is finished as soon as the white spot has become completely invisible, which occurs on the addition of 11.6cc. of tannin solution. It is therefore a very simple matter to estimate tannin in this way. It is only necessary to take the precaution of having the tannin solution to be tested of approximately 0.1 per cent. strength, and this is attained by using the following quantities with 100cc. of water: 1.5grm. European oak bark, 1grm. African bark, .5–6grm. Quebracho, .4–5grm. sumach, .25grm. catechu. The method allows of a determination to .5 per cent., and is completed in a few minutes. As gallic acid has not the same value for tanning as that precipitable by albumen, the analysis of this acid is of importance. A modification of the above process may be used. An aqueous extract of the raw material is made so that 100cc. water contain 2grms. of gallic acid. After diluting 50cc. to 100cc. with water, the quantity of Fe_2Cl_6 is determined necessary to produce complete opacity. In the remaining 50cc. 2grms. of scraped skin previously softened in water and dried between linen are added. After two hours the liquid is filtered through linen washed with water, 10cc. of 1 per cent. solution of pure tannin added, and diluted to 100cc. with water. This liquid contains 1grm. tannin and gallic acid, or other compounds not precipitable by tannin. The difference in volume of the 1 per cent. tannin solution and that of the solution to be determined gives the quantity of gallic acid.—J. B. C.

The Detection of Honey adulterated with Starch or Cane-sugar. H. Hager. Pharm. C. H. N. F. 1885, 6, 327.

THE following qualitative method has been proposed by the author:—

1. Starch-sugar or maize-starch syrup. 1–2cc. of 25 per cent. clear filtered honey solution are introduced into a test glass, and covered then carefully with about 5cc. absolute alcohol. With pure honey, the alcohol layer remains clear; with honey containing starch-sugar, or maize-starch syrup, the contact layer becomes milky white and retains this milkiness.

2. Cane-sugar or beetroot-sugar. 1.5 to 2cc. of concentrated sulphuric acid are introduced into a test glass 1cm. wide, and this is covered with 5cc. of a solution containing 25 per cent. of honey. The honey solution is not coloured at once at the layer of contact, and within an hour, yellow or light brown. In the presence of cane-sugar the contact layer is coloured brown at once, and after an hour almost black.—J. B. C.

The Iodine Test for Peppermint Oil. G. Koll. Pharm. C. H. F. 1885, 6, 467.

IN the German pharmacopœia II. it is stated, that by moistening powdered iodine with peppermint oil, there should be no rise of temperature. The author has tested different kinds of peppermint oil and found that with ol. menth. ppt. gallicum the temperature rose to 41°, with mitcham oil to 44°, and with German oils to as much as 54°. The clause would therefore read more correctly

thus:—that "In contact with iodine no strong heating or violent reaction should occur."—J. B. C.

Estimation of Oils which contain Unsaponifiable Fats. Th. Morawski and H. Demski. Dingl. Polyt. J. 258, 39.

COMPLETE separation of the liquid layers obtained by treating the saponified liquid with volatile solvents is often a matter of difficulty. 10grms. of the oil are treated with 50cc. of alcohol, and 5grms. KOH dissolved in the smallest quantity of water added, and the whole heated for half-an-hour with inverted condenser, 50cc. of water are added, and the mass allowed to cool. It is then shaken in a separating funnel with petroleum ether, and after the liquids have separated, the under-layer is removed, the petroleum layer is repeatedly washed with water, the washings being kept apart and separated as completely as possible from the ether. Instead of allowing the ether to run directly into the weighing bottle, it is first drawn off into a dry flask. If now the ether is transferred to the tared bottle, any drops of water will remain behind. The liquid, which has been once treated with ether, is again extracted in the same way, and the ether transferred to the weighing flask. To detect quickly if the nonsaponified fat is resin or mineral oil, it is shaken with an equal volume of acetone. If both liquids mix completely, it is a resin oil, or a mixture with a small proportion of mineral oil; if not, it is a mineral oil or a mixture with a small quantity of resin oil. Alcohol of sp. gr. .95 may be used, in which resin oils sink, whereas mineral oils do not. The determination of the vegetable oil present in the mixture with the mineral or resin oil can either be effected in the original mixture (by iodine and saponification) or with the fatty acids, which after separating the nonsaponifiable fat, are precipitated with an acid. This experiment may be extended to the saponification value, the melting and freezing point and the determination by iodine, according to Hübl's method. By the latter method the iodine, for the free fatty acid, must be first determined, as Hübl only determined it for neutral fats. For these determinations it is only necessary to act directly on the fatty acids with Hübl's iodine solution. If it is required to calculate the iodine amount I of the saponifiable fat from the amount I_2 of the original mixture of the separated nonsaponifiable fats and I_1 of the mixture, this may be done by the following equation: $I = (100I_1 - bI_2) : a$, in which a is the percentage of saponifiable and b that of the unsaponifiable fats. The first method is, however, to be preferred.—J. B. C.

Determination of Nitrogen in Organic Substances by Kjeldahl's Method.

THE method of Kjeldahl, published in detail in *Zeits. Anal. Chem.* 22, 366, is as follows:—

About one gramme of substance is placed in 100cc. flask, and 10cc. of strong H_2SO_4 , together with P_2O_5 added, and the mass then heated on wire gauze just below its boiling point until the original dark mass changes to a light yellow or colourless solution. Powdered KMnO_4 is then added in small portions at a time, but rapidly. It is advisable to sift it into the flask through a sieve of wire gauze. The oxidation is complete when a green colour appears. The mass is then warmed gently over the flame for 5–10 minutes, and after cooling transferred to a distilling flask of three-quarters litre capacity, to which a bent tube and condenser is attached, and an Erlenmeyer flask of one-quarter litre capacity placed as receiver, containing 10–40cc. of standard HCl solution. An excess of caustic soda of sp. gr. 1.3 is introduced, and the ammonia distilled off and determined in the receiver by titration. Slight modifications of this method have been recommended by various chemists. Wilfarth (*Chem. Centr.* 16, 17) uses a mixture of eight parts cone. H_2SO_4 , two parts fuming H_2SO_4 , and one part P_2O_5 ; he also adds .5 to 1grm. $\text{CuSO}_4 + \text{H}_2\text{O}$ or H_2O .

Pfeiffer and Lehman (*Zeits. Anal. Chem.* **24**, 388—393) modify the distilling apparatus so as to prevent any of the alkaline liquid being carried over, by interposing between the flask and the receiver an arrangement shown in the annexed figure, *c* being a perforated platinum cone surmounted by glass beads.

FIG. 1.

The above method has been the subject of a critical examination by Märcker and his assistants (*Zeits. Anal. Chem.* **23**, 553—557), who have analysed sixty-five different substances, and compared the results with those obtained by the method of Will and Varrentrap. The average difference amounts to 0.84 per cent., the higher result being obtained in the majority of cases by Kjeldahl's method.

FIG. 2.

The following are the advantages attributed by the authors to the latter method:—

1. It is less expensive, and there is a considerable saving in time, as a large number of determinations may be simultaneously carried out without close attention.
2. It is not requisite that the substance should be finely pulverised, and liquids may be quite as readily analysed as solids.
3. The distillate in the final operation is colourless, and therefore rosolic acid may be used and the titration carried on by gaslight.

For ordinary organic substances not more than one gramme should be taken; for manures 1.5 grm.

The authors supplement their results with the following modifications, which they recommend:—

The substance is covered with 20cc. of a mixture of four volumes concentrated pure H_2SO_4 , one volume fuming H_2SO_4 , and then two grammes of P_2O_5 are added. The mass is at first heated with a small flame to prevent frothing, which occasionally occurs with fat-foods. The mass is then well boiled, a process which the authors consider indispensable, and not as Kjeldahl recommends. The boiling is continued until the liquid attains a Rhine wine colour; or, at most, a faint red. The time required varies from half-an-hour, in the case of manures, to two hours, for foods; and 4—5 hours for blood, etc. The amount of NaOH recommended is such that after neutralising the acid with NaOH solution of 50° B. about 15cc. remain in excess. In washing the liquid into the distilling flask, an excess of water should be avoided. The amount of liquid should not exceed 200—250cc. By this means the whole of the NH_3 is driven over in half-an-hour. Where a number of determinations have to be performed simultaneously, the apparatus as shown in the diagram is employed.

Fig. 2 shows the apparatus in which the first portion of the operation is carried on, and consists of an iron tray with seven holes, in which the flasks containing the substance and sulphuric acid mixture are heated. Fig. 3 represents an iron stand provided with holes, upon which the flasks protected from the flame by wire gauze are placed. The condenser is an oblong box of tinned iron. Bohemian is used in preference to ordinary glass, as the alkali in the former is not dissolved by steam.—J. B. C.

Ammonia as a Reagent for Double Ketones which have the structure $CO : CO = 1 : 4$. Ludwig Knorr. *Ber.* **19**, 46—49.

THE author has shown (*Ber.* **17**, 2869; **18**, 300, 1558) that ammonia and primary amines act on diaecosuccinic ether with formation of pyrrol derivatives. Paal (*Ber.* **18**, 367, 2251) and Ledner and Paal (*Ber.* **18**, 2591) have observed that ammonia reacts similarly with acetophenone-acetone, acetylacetone, and acetophenone-

FIG. 3.

acetic ether. The reaction, therefore, appears to be a general one for double ketones of the formula—

The pyrrol derivatives so formed, when boiled with a dilute mineral acid, colour a pine shaving a deep red, and the reaction is so delicate that the merest trace of the pyrrol derivative, even in presence of other bodies, may be detected by it. Since also the double ketones, which have the structure $CO : CO = 1 : 4$, are readily converted by ammonia into pyrrol derivatives, such ketones

may be at once detected by this reaction. The ketone is dissolved in glacial acetic acid, and is boiled with a solution of ammonia in excess of acetic acid; the mixture is then boiled with dilute sulphuric acid, and the pine shaving introduced. The author succeeded in detecting the presence of 1mgm. of diaceto-succinic ether in a solution of 1 : 5000.

The value of the reaction in determining the constitution of compounds is shown by the following instance :—Bromo-levulinic ether may be represented by either of the three structural formulæ—

By the action of sodaceto-acetic ether one of the three following bodies must be formed :—

The compound formed shows the above-mentioned reaction, and must, therefore, be represented by the formula 1 or 2. But the first appears improbable when the action of the halogen elements on aceto-acetic ether is taken into account, and the author, therefore, adopts the second formula as correct, and names the condensation product α - β -diaceto-glutaric ether. The ether boils between 240° and 250° under a pressure of 140mm., with partial decomposition. By the action of ammonia and excess of acetic acid, after boiling a few minutes, dimethylpyrrolecarboxyl-acetic ether—

is obtained in the form of lustrous scales melting at 109–110°. The acid was also prepared from the ether by saponification with dilute caustic soda. It melts at 196° with rapid evolution of carbonic anhydride, the residual oil being probably trimethylpyrrol. The ether, the acid, and the pyrrol all show the reaction with pine shavings.

—S. Y.

New Books.

LESSONS IN ELEMENTARY CHEMISTRY—INORGANIC AND ORGANIC. By Sir HENRY E. ROSCOE, LL.D., F.R.S. New Edition. London: Macmillan & Co., 1886.

No description of this well-known work is required: suffice it to say, that whilst preserving carefully the concise form and treatment so necessary in a book to be used in schools as well as in the colleges, certain important additions have been made by the author in reference to new facts brought to light since the last reprint in 1877.

ORGANISCHE FARBSTOFFE. Von Dr. R. NIETZKI. Breslau: Verlag von Edward Trewendt, 1886. London: H. Grevel, 33, King Street, Covent Garden.

SMALL OCTAVO volume, bound in cloth, price 4s. (4 Mark). The work treats both of the natural and artificial colouring matters with great conciseness, but with copious references to original sources. The mode of treatment is gleaned from the arrangement

of the subject-matter in the table of contents (Inhaltsverzeichnis), of which the following is an outline :—

(A) NATURAL DYES AND COLOURS: (B) DYES AND COLOURS ARTIFICIALLY PREPARED.—I. Nitro-compounds. II. Azo-colours—(1) *Amidoazo-compounds*; (2) *Oxyazo-compounds*; (3) *Tetraazo-colours* or *Disazo-compounds*. III. Colours of the Triphenylmethane Series—(1) *Diamidotriphenylmethane colours*; (2) *Triamidotriphenylmethane colours*; (3) *Rosolic acid colours*; (4) *Phthalic acid colours*. IV. Indamines and Indophenoles. V. Safranines and Allied Dye-stuffs. VI. Aniline Black. VII. Indulines and Nigrosines. VIII. Quinoline and Acridine Colours. IX. Anthraquinone Colours.

Monthly Patent List.

I.—GENERAL PLANT, APPARATUS, AND MACHINERY.

APPLICATIONS.

1886.

2661 J. Dawson, Bury. Improvements in steam blowers for producing air draught in furnaces, and for other purposes. February 24

2721 R. de Soldenhoff, London. Improvements in furnaces for the desiccation, incineration, and carbonisation of precipitants or solids resulting from sludge or other substances liable to putrefy, as also for the treatment of coal or carbonaceous substances. Complete specification. February 24

2739 J. Merritt, Birmingham. Improvements in the construction of pumps for vinegar and other acid liquids. February 25

2861 F. Windhausen, Halifax. Improvements in apparatus for refrigerating purposes. February 27

2875 A. Milne, J. F. Gray, and A. S. Tomkins, London. An improvement in smoke consuming apparatus. February 27

2927 H. E. Newton, London—Communicated by E. Theisen, Germany. Improvements in apparatus for cooling and condensing purposes. March 1

2962 J. A. Muller, London. Improvements in apparatus for measuring and registering currents of water or other liquids, and also fluids or gases. March 2

2973 W. R. Lake, London—Communicated by W. O. Webber, United States. Improvements in centrifugal pumps. March 2

2992 J. Newton, Longport. Improvements in pipes and taps for filter presses. March 3

3020 W. Beesley and J. Beesley, London. Improvements in steam-boilers applicable for utilising the waste heat from puddling, forge, mill, or other furnaces. March 3

3023 J. Murrie, Glasgow. Improvements in apparatus for indicating temperature or pressure. March 3

3099 R. McLaren Young, London. Improvements in steam-boiler and other furnaces. March 4

3134 J. Howarth, Manchester. Improvements in apparatus for cooling, warming, moistening, or saturating air. Complete specification. March 5

3150 J. B. Alliot and G. P. Haughton, London. Improvements in or connected with centrifugal drying machines. Complete specification. March 6

3266 H. Callas, London. Improvements in fuel supports for steam boiler furnaces. March 9

3270 C. S. Madan, Manchester. Improvements in injectors for raising and forcing fluids and feeding steam boilers. March 9

3287 W. R. M. Thomson, Glasgow—Communicated by O. Coldewe, Germany. Improvements in smoke-consuming furnaces. March 9

3300 J. H. Campbell, London. Improvements in method of and apparatus for utilising binary liquids, more especially aqua ammonia, as a motive power. Complete specification. March 9

3326 A. M. Clark, London—Communicated by P. Oriollo, France. Improvements in, and in apparatus for, distilling water. March 9

3393 J. Lysaght and J. Lysaght, Limited, London. Annealing apparatus. March 10

3442 G. H. Moore, Liverpool. Methods of and apparatus for refining fluids. Complete specification. March 11

3581 H. McDowell, London. Improvements in appliances for consuming smoke in boilers, furnaces, and the like. March 13

3587 J. R. Alsing, London. Improved mode of triturating and apparatus for such purpose. Complete specification. March 18

3589 H. E. Newton, London—Communicated by R. A. Chesebrough, United States. Improvements in hot-air furnaces. Complete specification. March 18

3597 W. Sellar, London. Improvements in apparatus for heating, purifying, and filtering water used for feeding steam

boilers; also applicable for filtering the feed water for pumps, or suction pipes in sinking pits, wells, dry docks, and the like; and for filtering water generally. March 19
 3964 G. P. Keldern, London—Communicated by C. A. Johansson, Sweden. An improved centrifugal separating machine. Complete specification. March 20
 4013 C. Little, Chesterfield. Improvements in pumps and air compressors. March 22

COMPLETE SPECIFICATIONS ACCEPTED.*

1885.

3896 J. H. Johnson—Communicated by M. Perret. Improvements in furnaces for burning pulverulent materials; applicable also to gas producers. March 12
 3654 H. J. Haddan—Communicated by A. Liedbeck. Distilling apparatus. March 5
 5816 F. J. Austin and S. Low, jun. Prevention of formation of boiler crust. March 12
 6276 C. C. Carpenter. Retort lid fittings. March 23
 7389 W. P. Thompson—Communicated by F. C. Glaser. Apparatus for separation of suspended matters from water, etc., and removal of the resultant sediment. March 12
 13466 E. Solvay. Apparatus and process for producing, applying and keeping up extreme temperatures. March 9

1886.

266 R. Wainwright and W. Wainwright. Construction of furnaces for effecting the consumption of smoke. March 19
 703 L. T. Karras. Apparatus for lifting or handling crucibles, etc. March 5
 1436 H. Kosiecke. Smoke-consuming furnaces. March 2
 1517 J. S. Badia. Automatic apparatus for generating gases. March 19
 2252 L. Douillet. Metallic casks or drums. March 16

II.—FUEL, GAS, AND LIGHT.

APPLICATIONS.

2618 C. Blagburn, London. Improvements in the method of and apparatus for injecting petroleum and other liquid fuel into furnaces. February 23
 2751 J. C. Stitt, Liverpool. Improvements in connection with the combustion of fuel in furnaces of steam generators and in the furnaces employed therein. February 25
 2766 W. L. Wise, London—Communicated by F. J. Lothamer, France. Improved portable apparatus for the manufacture of gas. February 25
 2803 J. Lilley, London. Improvements in apparatus for the manufacture of artificial fuel. February 26
 2807 S. W. Allen and G. Breditt, London. Improvements in apparatus for the manufacture of artificial fuel. February 26
 2836 R. C. Sinclair and S. W. Snowden, London. Improvements in means for effecting the consumption of smoke, and economy of fuel from and in the furnaces or fireboxes of locomotive steam-engines and the like. February 26
 2892 H. Bowater, Cradley. The purification of coal gas. March 1
 2904 F. J. Jones, London. Improvements in gas producers, whereby the whole of the combustible elements in the original coal, etc., are converted into permanent gases. March 1
 2950 J. Parkes, Birmingham. Improvements in apparatus for enriching illuminating gas. Complete specification. March 2
 3057 J. A. Yeadon and R. Middleton, Leeds. Improvements in machinery or apparatus for the manufacture of artificial fuel or other materials. March 4
 3058 J. A. Yeadon and R. Middleton, Leeds. Improvements in machinery for the manufacture of artificial fuel or other similar materials. March 4
 3074 W. Smith, London. A simple way of burning hydrocarbons in a furnace after the manner of a coal fire. March 4
 3320 H. H. Salomons, London. Improvements in means for securing the lids or covers to the mouthpieces of gas retorts. March 9
 3381 J. A. Yeadon and R. Middleton, Leeds. Improvements in machinery for the manufacture of artificial fuel or other similar materials. March 13
 3392 O. Imray, London—Communicated by C. A. von Welsbach, Austria. Improvements in illuminant appliances for burners. March 13
 3697 F. Windham, London. An improvement in the manufacture of gas for use in gas-engines. March 16
 3767 J. H. W. Stringfellow, London. Improvements in the method of and apparatus for burning hydrocarbon and other oils. March 17
 3771 W. Edwards, London. A new or improved mode of and means for the manufacture and utilisation of gas from hydrocarbons. March 17
 3796 G. Parkes, Birmingham—Partly communicated by A. Parkes, United States. Improvements in producing heat and light for cooking, lighting, and other purposes. March 18
 3883 W. Grierson, Glasgow. Improvements in electrostatic induction machines for lighting gas, applicable also for other electrical purposes. March 19

* The dates given are the dates of the Official Journals in which acceptances of the Complete Specifications are advertised. Specifications thus advertised are open to inspection at the Patent Office immediately, and to opposition within two months of the said dates.

COMPLETE SPECIFICATIONS ACCEPTED.

1885.

2986 J. G. Lorrain. Improvements in lighting. March 5
 4798 S. Butler. Manufacture of artificial fuel, and machinery therefor. March 9
 5399 P. Tarbutt. Apparatus for combustion of liquid hydrocarbons. March 2
 5980 A. Wilson. Gas producers. March 23
 6881 J. Y. Johnson—Communicated by La Société Anonyme des Forges et Chantiers de la Méditerranée. Apparatus for manufacturing blocks of artificial fuel. March 23
 12540 H. M. Morrison—Communicated by J. G. Hathaway. Apparatus for pulverising fuel and feeding it to furnaces, etc. March 23
 15367 G. Anderson. Apparatus for distribution of gas and air in regenerative and other furnaces wherein gaseous fuel is used. March 16

III.—DESTRUCTIVE DISTILLATION, TAR PRODUCTS, ETC.

APPLICATIONS.

3495 L. M. Becker, London. An improved method of treating hydrocarbon oils and petroleum residuums. March 12
 5738 G. T. Beilby and J. B. McArthur, St. Kitts, N.B. Utilisation of waste hydrocarbons. March 17

COMPLETE SPECIFICATIONS ACCEPTED.

1885.

10438 H. J. Haddan—Communicated by J. Quaglio. Apparatus for compressing coal, and introducing the same into coke ovens. March 16

1886.

1016 H. Kenyon. Distillation and decomposition of coal, shale, etc., to obtain illuminating gas and other matters. March 9
 1017 H. Kenyon. Ovens or retorts, etc., for use in distillation of coal, shale, etc. March 2

IV.—COLOURING MATTERS AND DYES.

APPLICATIONS.

2878 A. M. Clark, London—Communicated by A. Muller-Jacobs, through Wirth & Co., Germany. Improvements in the manufacture of colouring matters and vehicle therefor. February 27
 3198 J. Y. Johnson, London—Communicated by The Actien-gesellschaft Farbenfabriken vormals F. Bayer & Co., Germany. Improvements in the manufacture of azo dyes and benzidine and tolidine mono-sulpho acids. March 6
 3247 M. B. Vogel, London. Processes for producing oxalates of antimony suitable as mordants in dyeing and printing. March 8
 3407 J. Y. Johnson, London—Communicated by The Farben-fabriken vormals F. Bayer & Co., Germany. Improvements in the manufacture of dyes. March 10
 3552 J. B. Cohen, Manchester. Improvements in or appertaining to the separation of the amines or organic bases. March 13
 3890 T. Carnelley, Dundee. The preparation of para-amido-diphenyl sulphonic acid. March 19

COMPLETE SPECIFICATION ACCEPTED.

1886.

2083 W. R. Lake—Communicated by A. E. Spencer. Blueing for laundry purposes, and means for use of the same. March 12

V.—TEXTILES: COTTON, WOOL, SILK, ETC.

APPLICATIONS.

2616 H. J. Haddan, London—Communicated by the United States Waterproofing Fibre Co., Limited, United States. Improvements in the method of and composition for treating textile fabrics, cordage, ropes, nets, and similar materials. Complete specification. February 23
 2656 O. W. G. Briegleb, London—Communicated by Dr. J. F. Riep, Holland. Improvements in the treatment of ricea and other fibres. February 23
 2660 K. T. Sutherland, Manchester. An improved material for sizing yarn and for finishing piece goods. February 24
 2805 W. Pollitt, Chichester, Yorks.; A. Stevenson, Osssett, Yorks.; and J. Priestley, Sandal, Yorks. A new means of treating waste fibrous substances, and utilising the whole or portions thereof. February 26
 2817 G. W. Hargreaves Brogden and E. Casper, London—Communicated by E. Frémy and Y. Urbain, France. Improvements in obtaining and treating fibres from the backs of plants of the Urtica family and the like. February 26
 3065 R. W. Thom, Manchester. Improvements in finishing textile fabrics and in apparatus therefor. March 4

- 3095 G. F. Redfern, London.—Communicated by E. Chevallot, France. Improvements in waterproofing fabrics. March 4
 3098 W. H. Murray and R. J. Young, London. A solution rendering textile fabrics and other materials both fire-proof and water-proof. March 4
 3483 G. Lendrum and D. F. Cocks, Huddersfield. A new or improved treatment or "finish" of stockinette fabrics. March 12
 3532 J. Hibbert, Halifax. Improvements in apparatus for controlling and regulating the flow and supply of size to and from boiling pans of machines employed for sizing yarns. March 12
 3555 A. B. O'Connor and J. H. Wilson, London. Improvements in apparatus and method of treating wool and other similar substances for the purpose of cleansing, extracting, and recovering the fats and other products therefrom. March 13
 3755 W. S. Johanson, Liverpool. Improvements in the manufacture or softening of linen, hemp, jute, or other yarns. March 17
 3880 H. Rouse, Bradford. A new fabric for dress goods and other clothing purposes. March 19
 3937 H. Birkbeck, London.—Communicated by T. F. Peppé, India. Improvements in treating and preparing "Tussur" and other wild silk cocoons, and in the application of the silk obtained therefrom to the manufacture of lace, knitted warp, and other fabrics. March 20
 3980 F. Robinson, Leeds. An improved process in the manufacture of plush and other pile fabrics by the double cloth method. March 22

COMPLETE SPECIFICATIONS ACCEPTED.

1885.

- 14393 M. Iwand and F. Kühne. Treating webs, wool rags, waste, etc., to be carbonated in the wet way; and drying the same. March 12

1886.

- 1896 W. R. Lake.—Communicated by H. R. Randall. Treatment of silk cocoons, raw silk, etc. March 9
 2206 H. H. Lake.—Communicated by F. G. Sargeant and A. C. Sargeant. Drying wool and other fibrous materials; and apparatus therefor. March 16
 2616 H. J. Haddon.—Communicated by the United States Waterproofing Fibre Co., Limited. Method and composition for treating textile fabrics, etc. March 23

VI.—DYEING, CALICO PRINTING, PAPER STAINING, AND BLEACHING.

APPLICATIONS.

- 3247 M. B. Vogel, London. Processes for producing oxalates of antimony suitable as mordants in dyeing and printing. March 8
 3248 M. B. Vogel, London. Improvements in mordanting vegetable fibres, yarns, and fabrics. March 8
 3732 H. Kershaw, Manchester. Improvements in dyeing textile goods and materials. March 17
 3744 T. Holliday, London. Improvements in dyeing wool and other textile animal fibres. March 17

COMPLETE SPECIFICATIONS ACCEPTED.

1885.

- 6018 T. J. Hutchinson, Bury. Process and apparatus for treating greasy waste preparatory to bleaching. March 23
 6331 E. Taylor. Purifying and decolouring water in which silk and other fibrous materials have been boiled with soap, and the refuse, liquid or dye, in which silks, etc., have been dyed or cleansed; and recovering useful products therefrom. March 16
 6888 W. R. Lake.—Communicated by The Prag Smichower Kattun Manufactur and F. Storck. Apparatus for fixing colours printed on cotton fabrics, and for washing the same. March 23

1886.

- 1424 W. Birch. Apparatus for washing, soaping, dyeing and dunging woven fabrics. March 2

VII.—ACIDS, ALKALIS, AND SALTS.

APPLICATIONS.

- 2739 J. Merritt, Birmingham. Improvements in the construction of pumps for vinegar and other acid liquids. Feb. 25
 2779 H. Whitehead, R. Hodgson, and W. H. Green, Longport. Improved apparatus for making boiled, common, and fishery salt from brine by steam. February 26
 3063 J. M. Walton, Manchester. Improvements in the manufacture of bisulphites from alkaline bases, and in apparatus employed in such manufacture. March 4
 3220 A. Dempster, Halifax. Improvements in apparatus for distilling ammoniacal liquor for the purpose of producing sulphate of ammonia. Complete specification. March 8
 3231 J. Gale, London. Improvements in apparatus for collecting and absorbing carbonic acid gas and other noxious gas or gases. March 8
 3238 L. Mond, Liverpool. Improvements in obtaining ammonia, chlorine, and hydrochloric acid from ammonium chloride. March 8

- 3322 B. J. B. Mills, London.—Communicated by The Verein für Chemische Industrie, Germany. An improved process of producing chlorine, and chlorine and ammonia. Complete specification. March 9

- 3371 J. Whittle, London. Improvements in and apparatus for the manufacture of acetic and other similar acids. March 10
 3406 E. F. Trachsel, London. An improved process for the production of carbonate of sodium, or of potassium and hydrate of strontium, or of barium. March 10
 3556 J. H. Johanson, London.—Communicated by E. Hermite, France. Improved means for producing ozone and hydrogen suitable for bleaching purposes. March 20
 3557 J. H. Johnson, London.—Communicated by E. Hermite, France. Improved means for producing chlorine compounds suitable for bleaching purposes. March 20

COMPLETE SPECIFICATIONS ACCEPTED.

1885.

- 4136 C. Wigg. Apparatus for manufacture of carbonate of soda and caustic soda. March 5
 5260 J. Brock and W. A. Rowell. Manufacture of chromates and acid chromates. March 2
 5280 W. L. Wise.—Communicated by R. Radot. Decarbonation of various earthy carbonates; and apparatus therefor. March 12
 5620 C. Wigg. Utilising certain residuals from the manufacture of copper and alkali. March 12
 5919 J. F. Chance. Production of nitrate of ammonia and bicarbonate of soda. March 16
 5920 J. F. Chance. Purification of alkaline tank or vat liquors. March 16

1886.

- 2262 E. Luhmann and C. G. Ronneuhöller. Measuring apparatus for liquid carbonic acid. March 16

VIII.—GLASS, POTTERY, AND EARTHENWARE.

APPLICATIONS.

- 2799 A. W. Lake, London.—Communicated by T. Hyatt United States. Improvements in exfoliated or crystallised, glass, and in means, modes, and processes therefor. Feb. 26
 2855 H. S. Sant and S. Sant, Longton. A new process for the decoration, mosaic or otherwise, of all kinds of pottery-ware, by the use of skeletons or fibres of leaves or other parts of plants, trees, or vegetables, or of insects, or anything capable of being skeletonised. February 27
 3096 G. F. Redfern, London.—Communicated by A. V. Morizot, France. An improved process for colouring ceramic products whilst in a cold state. March 4
 3252 A. C. Henderson, London.—Communicated by L. Charmanier and S. de Cazenave, France. Improvements in the manufacture of stained glass windows, the said invention being also applicable to the decoration of other articles of glass or crystal. March 8
 3369 J. D. Denny, Ruabon. An improvement in embossed and geometrical tiles, also mosaics, and appliances for making the same. March 10
 3391 T. J. Payne, Romford. An improvement in the manufacture of fire-bricks, retorts, crucibles, and other fire-ware goods. March 10
 3393 J. Lysaght and J. Lysaght, Limited, London. Annealing apparatus. March 10
 3419 W. Cartledge and H. Cartledge, Liverpool. Improvements in enamel, lustre, and hardening kilns used in the manufacture of pottery-ware. March 11
 3420 G. A. Jarvis, Wellington, Salop. Manufacture of improved basic bricks
 3421 G. A. Jarvis. Improvements in the manufacture of basic bricks. March 11
 3419 C. E. Davis, London. Improvements in tiles for roofing. March 11
 3567 T. Stanway and F. Spencer, Longport. An improved method of testing the heat of "enamel" and other similar kilns. March 13
 3618 J. Critchlow, London. An improved mode or method of hydraulic filter-press for the production of potters' clay and other purposes. March 15
 3372 W. E. Chance, London. New or improved machinery for the manufacture of sheets of rippled glass. March 20

COMPLETE SPECIFICATIONS ACCEPTED.

1885.

- 5175 W. M. Brown and H. Clayton, Halifax. Fireclay, earthenware, or stoneware baths. February 26
 6463 J. G. Sowerby. Construction of moulds for manufacture of glass-ware. March 5
 6337 J. G. Sowerby. Moulds for articles of glass or other ware. March 2

IX.—BUILDING MATERIALS, CLAYS, MORTARS, AND CEMENTS.

APPLICATIONS.

- 2659 C. Spackman, Sibley, Loughborough. An improved system of drying the prepared mixture of raw materials for the manufacture of Portland cement. Complete specification. February 24
 3102 T. Weekes, London. Improvements in the manufacture of Portland cement. March 4

- 3171 J. Prince and W. Johnson, Leeds. Improvements in the mode of treating, mixing, and cleaning clays and other materials, and in machinery employed therefor. March 6
- 3217 J. B. Hannay, Glasgow. Improvements in treating sewage and making cement. March 8
- 3462 S. Collier, jun., London. Improvements in disintegrating or pulverising machines for the manufacture of lime and cement. March 11
- 3832 W. E. Constable, London. Improvements in the manufacture of artificial asphalt. March 18
- 3909 H. Peters, Rochester. Improvements in the manufacture of Portland cement. (Previously included in No. 447, of 1886.) January 11
- 3961 S. Frankenberg, London. An improved cement or composition for use in laying or fixing wood and other pavements and blocks for mosaic work and the like. March 20

COMPLETE SPECIFICATIONS ACCEPTED.

1885.

- 6133 E. Cammiss. Means and apparatus for manufacture of bricks. March 2
- 6441 C. F. Foster. Paving of streets, etc., and manufacture of blocks therefor. March 23
- 13840 T. Hunter and J. G. Brown. Making and setting (in water) cement concrete blocks. March 2

1886.

- 1604 E. Ashby and A. Ashby. Cement kilns. March 9

X.—METALLURGY, MINING, Etc.

APPLICATIONS.

- 2865 F. Rosshardt, London—Communicated by S. Montagne, France. Improvements in the method of and means for extracting the tin from tinned sheet metal cuttings by means of hydrochloric acid gases. February 27
- 2867 J. H. Johnson, London—Communicated by La Société Anonyme de Commeny-Fourchambault, France. Improvements in the manufacture of iron and steel. February 27
- 2870 R. Stone, London. Improvements in smelting, and machinery and appliances for carrying same into effect. February 27
- 3138 G. T. Lewis, London. Improvements in the smelting of tin ore, and recovering tin from tinned sheet iron scraps. March 5
- 3143 J. A. du Reitz, London. Improvements in coating sheet iron and other materials with zinc, and in apparatus therefor. March 5
- 3293 T. C. Huntington and M. Chiapponi, London. Improvements in effecting the extraction of antimony from ores or compounds containing the same. March 9
- 3346 F. W. Martino, London. New or improved alloys of zinc. March 9
- 3379 J. H. Thomas, London. Improvements in or applicable to the manufacture of tin andterne plates, and sheet metal or coated sheets. March 10
- 3380 W. E. Gedde, London—Communicated C. M. Pielsticker, Russia. Improvements in the machinery and process for the manufacture of plates and bars of steel, and of other metal. March 10
- 3389 J. E. Craig, London. Improvements in the manufacture of sheet iron. Complete specification. March 10
- 3448 F. Brain, London. A novel method of shot-firing and blasting in mines, by the agency of electricity. March 11
- 3457 W. D. Allen, London. Improvements in furnaces for melting or melting and treating pig iron, and in feeding or charging the same. March 11
- 3498 E. Fox, London. Improvements in casting metals in chill moulds, and in means or apparatus employed therein. March 12
- 3540 A. M. Clark, London—Communicated by La Société Scola et Ruggieri, France. An improved electric fuse for blasting purposes. March 12
- 3632 L. A. Groth, London—Communicated by C. Becksteio, Germany. A new or improved glowing powder for hardening metals. March 15
- 3674 A. F. Harris, Birmingham. Improvements in electroplating apparatus. March 16
- 3684 C. Clarke, Birmingham. A new or improved process of producing a "coloured gold" surface on articles of gold or other metal or alloy. March 16
- 3702 E. B. Parnell, London. An improved process of treating certain descriptions of auriferous and argentiferous material for the purpose of facilitating the separation of the metals contained therein. Complete specification. March 16
- 3746 J. F. Hall, Sheffield. Improvements in armour plates. March 17
- 3770 J. B. Spence, London. Improvements in obtaining aluminium from salts of alumina. March 17
- 3836 A. Kurzwehnart and E. Bertrand, London. An improved mode of and apparatus for casting ingots of steel or ingot metal. March 18
- 3867 A. M. Clark, London—Communicated by H. Harnet, France. An improved basic lining for metallurgical apparatus. March 18
- 3878 R. Hanson and J. Fernie, Sheffield. An improved open hearth furnace for steel melting and other purposes. March 19
- 3907 W. F. Richards, London. An improvement in the manufacture of tin plates. March 19

- 3985 C. E. Steinweg, London. A process for plating metals and metallic alloys. Complete specification. March 22
- 3986 J. M. White, Darlington. Improvements in furnaces for the manufacture of metallic sleepers. March 22

COMPLETE SPECIFICATIONS ACCEPTED.

1885.

- 4741 F. J. P. Cheesbrough. Manufacture of iron and steel direct from the ore, with gaseous fuel; and apparatus. February 26
- 6039 J. Heath and W. Frost. Method of blasting and shot firing mines. March 19
- 6317 G. M. Edwards. Machinery and appliances for dressing, etc., mineral ores. March 9
- 6873 J. Giers. Manufacture of steel. March 16
- 6894 J. McCulloch. Preparing ores, oxides, or compounds of iron for smelting or reducing. March 16
- 7510 P. Jonson—Communicated by J. Omholt and The Chemische Fabrik Gossnitz. Continuous manufacture of light metals by application of electrolysis; and apparatus therefor. March 23
- 7571 G. A. Jarvis and A. E. Tucker. Manufacture of steel converter bottoms, plugs, or blocks. March 12
- 7740 J. M. H. Munro. Treating basic cinder to obtain products useful as manures, etc. March 9

XI.—FATS, OILS, AND SOAP MANUFACTURE.

APPLICATIONS.

- 2762 E. Edwards, London—Communicated by L. Rivière, France. An improved process for the saponification of fatty bodies. February 25
- 2800 A. E. Scott, London. A cleansing fluid. February 26
- 2821 B. Nickels, London. Improvements in the treatment and purification of spent soap lyes and crude glycerine obtained therefrom. February 26
- 3030 J. Longmore, Liverpool. Improvements in the treatment or utilisation of cotton-seed oil residue. March 3
- 3512 E. J. Digby, London. A lubricant. March 12
- 3518 B. J. Hicks and J. Kirkwood, London. An improved lubricating composition. March 12
- 3644 A. W. McIlwaine, London. Improved means applicable for use in extracting oils by volatile solvents. March 15
- 3749 A. F. Craig, A. Neilson, and J. Snodgrass, Glasgow. Improvements in apparatus for separating mineral or other oil from oils or substances of different specific gravities. March 17
- 3987 J. Townsend, Glasgow. Improvements in making soaps. Complete specification. March 22

COMPLETE SPECIFICATIONS ACCEPTED.

1885.

- 3725 M. G. Coltart and J. Menzies, Glasgow. Manufacture of oleaginous compounds for batching wool, etc. March 16
- 6562 C. D. Abel—Communicated by L. Hugues. Apparatus for subjecting neutral fatty bodies to the action of water at high temperature, and for the direct production of fatty acids and glycerine. March 19
- 7454 P. Brintini. Saponaceous material for washing purposes. March 16

1886.

- 1525 C. Fink. Lubricating compounds. March 2
- 1939 J. Whittle. Extracting oil or grease from cotton-waste, etc., and apparatus therefor. March 12

XII.—PAINTS, VARNISHES, AND RESINS.

APPLICATIONS.

- 2789 D. Swan, Glasgow. Improvements in obtaining pigments. February 26
- 3513 E. J. Digby, London. Steam boiler and iron varnish. March 12
- 3636 A. C. Ireland and J. R. Bowbeer, London. An improved composition or paint for preventing attachment of barnacles to the bottoms of iron and steel-plated ships. March 15

COMPLETE SPECIFICATIONS ACCEPTED.

1885.

- 6844 M. Schumann—Communicated by H. Graf. An improved metallic paint. March 19

1886.

- 1511 E. W. McClave. Distilling turpentine and purifying the crude products thereof. March 9

XIII.—TANNING, LEATHER, GLUE AND SIZE.

APPLICATION.

- 3511 J. S. Billwitter, London. Process for tanning skins. March 12

COMPLETE SPECIFICATIONS ACCEPTED.

1885.

- 11880 J. W. Davies. Industrial utilisation of leather waste. March 23

1886.

437 A. J. Hailes. Preparation of skins, kips, and hides, by improvement in the process of "puring" or "bating." March 5

1554 W. R. Lake—Communicated by W. M. Hoffmann. Improvements in "putting out" and "striking out" machines for the preparation of calf and other skins. March 2

XIV.—AGRICULTURE, MANURES, Etc.

COMPLETE SPECIFICATION ACCEPTED.

1885.

6153 W. Grimshaw. Treating and drying excreta, and manufacturing same into manure. March 5

XV.—SUGAR, STARCHES, GUMS, Etc.

APPLICATIONS.

2765 M. Kiefe, London. A process and apparatus for obtaining pure sugar from molasses. February 25

2812 C. D. Abel, London—Communicated by L. Markle, Germany. An improved internal coating for sugar moulds. February 26

3001 W. T. Crooke and A. A. Arnold, London. Improvements in the cleansing of "pockets" or bags employed in the manufacture of sugar, honey, or other like substances, and in the means employed therefor. March 3

3116 M. F. Heddle, D. C. Glen, and D. Stewart, Glasgow. Improvements in filtering and decolourising sugar, syrups, and other liquids, and in preparing a material therefor. March 5

3196 R. Englert and F. Becker, London. Improvements in the process of purifying saccharine juices. March 6

3556 E. Fahrig, Manchester. Improvements in the manufacture of sugar by electrolysis. March 13

3609 J. D. Scott and A. Scott, Glasgow. Improvements connected with vacuum pans for concentrating sugar solutions. March 15

3628 H. E. J. Selwig and B. C. A. C. Lange, Liverpool. Improvements in the manufacture of sugar blocks, and apparatus therefor. March 15

3727 H. H. Lake, London—Communicated by the Societe Nouvelle des Raffineries de Sucre de St. Louis, France. Improvements relating to the refining of sugar, and to apparatus therefor. Complete specification. March 16

COMPLETE SPECIFICATIONS ACCEPTED.

1885.

6358 L. Lefranc. Process for extracting juices, syrups, and molasses. March 5

7098 O. Korschelt—Communicated by H. Soxhlet. Manufacture of grape sugar. March 23

8843 G. M. Newhall and J. H. Tucker. Treating sugar and like substances, and apparatus therefor. February 26

1886.

1108 A. M. Clark—Communicated by J. J. Haug and C. Hoffmann. Manufacture of a substitute for caoutchouc and gutta-percha. February 26

1888 W. R. Lake—Communicated by F. O. Matthiessen. Filters and apparatus for purifying sugar-liquor. March 19

1889 W. R. Lake—Communicated by F. O. Matthiessen. Dischargers for filtering apparatus used in the purification of sugar-liquor. March 16

1890 W. R. Lake—Communicated by E. E. Quimby. Filtering apparatus for purifying sugar-liquor. March 16

1891 W. R. Lake—Communicated by R. C. Howes. Filtering apparatus for use in the purification of sugar-liquor. March 16

1914 J. McClure C. Paton. Triple effect evaporating apparatus used in the manufacture of sugar. March 23

XVI.—BREWING, WINES, SPIRITS, Etc.

APPLICATIONS.

2601 J. Wright, London. Improvements in the processes of distillation and rectification. Complete specification. Feb. 23

2629 A. W. Gillman, S. Spencer, and E. S. Spencer, London. Improvements in machinery or apparatus employed in steaming grain or cereals to be used in brewing, distilling, and vinegar making. February 23

2866 F. E. V. Beanes, London—Communicated by E. Beanes, France. Improvements in means for the treatment of liquids prior to their being bottled or enclosed for keeping. Feb. 27

3298 H. R. Matthews and C. G. Matthews, London. The aeration or supersaturation of definite or standard mixtures of pure and potable wines or spirits with spring water, or any natural or manufactured mineral water or beverage. March 9

3603 H. H. Lake, London—Communicated by J. W. Noll, Germany. An improved method of and apparatus for renovating or freshening beer or similar liquids. March 13

COMPLETE SPECIFICATIONS ACCEPTED.

1885.

4392 J. H. Johnson—Communicated by L. Morel. Apparatus for raising beer, etc. March 2

4988 H. J. Haddon—Communicated by P. Lauth. Apparatus for drying malt, etc. March 2

5647 G. Barker. Apparatus for aerating malt and other liquors. March 5

6213 J. C. Mewburn—Communicated by G. Noback and W. Gintl. Treating waste products from brewing and similar processes. March 2

7788 L. Cuisinier. Preventing from alterations the saccharification of amylaceous substances by malt. March 12

1886.

2601 J. Wright. Improvements in processes of distillation and rectification. March 23

XVII.—CHEMISTRY OF FOODS, SANITARY CHEMISTRY, DISINFECTANTS, Etc.

APPLICATIONS.

A.—CHEMISTRY OF FOODS.

2646 A. M. Clark, London—Communicated by A. L. Saint Aubin, France. An improved process and apparatus for treating coffee. February 23

2871 A. W. M. Leicester, London. A process for preserving fruits. February 27

2909 C. Hansen, London. Improvements in the treatment of rennet. March 1

3124 W. Garthwaite, Great Grimsby. Producing "fish-biscuit" for dogs, and food for poultry, game, etc. March 5

3191 A. T. Wedelin, London. Preserving animal and vegetable substances. March 12

3910 C. J. Henderson, Edinburgh. Preserving fish. March 20

B.—SANITARY CHEMISTRY.

2721 R. de Soldenhoff, London. Improvements in furnaces for the desiccation, incineration, and carbonisation of precipitates or solids resulting from sludge or other substances liable to putrefy, etc. Complete specification. February 24

2752 F. H. Colley, Sheffield. Improvements in the process of purifying sewage or drainage from tanneries, dye works, factories, or other sources. February 25

3217 J. B. Hannay, Glasgow. Improvements in treating sewage and making cement. March 8

3626 W. Berridge, Windsor. Sanitary improvements applicable to water-closets and urinals, etc. March 15

3730 C. W. Burton and F. T. Moison, London. Improvements relating to the purification of water. March 16

3731 C. W. Burton and F. T. Moison, London. Improvements relating to the purification of water, and to apparatus therefor. March 16

3826 J. G. Lorrain, London. Improvements in the formation of organic oxides, and in the oxidation of matter suspended or dissolved in liquids. March 18

3973 J. W. Slater, S. K. Page, W. Stevens, and The Native Guano Co., Limited, London. Improvements in the preparation of materials for use in the treatment of sewage and foul water. March 20

C.—DISINFECTANTS.

2780 J. G. Swan and R. M. W. Swan, Glasgow. A sheep dipping and disinfectant composition. Complete specification. February 22

3861 R. V. Tuson, London. Improved preparations to be used for the destruction of insects and parasites on sheep and other animals. March 18

COMPLETE SPECIFICATIONS ACCEPTED.

A.—CHEMISTRY OF FOODS.

1885.

5295 J. W. C. Meiler. Malt cocoa. March 2

6050 D. Ker. Manufacturing from cocoa in any form a paste soluble in cold water of any temperature. March 2

7056 H. T. Johnson. Vessels for keeping cool and preserving food. March 19

1886.

1112 W. A. Murray. Manufacture of butter. March 2

B.—SANITARY CHEMISTRY.

1885.

4981 F. J. Austin. Apparatus for disinfecting, deodorising, or precipitating purposes. March 12

5153 J. Hewes. Treatment of excreta and house sewage, and material and apparatus therefor. March 16

5172 L. Schroter. Apparatus and process for purifying and filtering waters. March 9

6653 T. Bradford. Disinfecting apparatus. March 16

1886.

1053 G. H. Leame. Method of continuous filtration, applicable to the purification of sewage. March 5

C.—DISINFECTANTS.

1885.

12985 W. D. Borland. Obtaining granulated antiseptic preparations. March 2

XVIII.—ELECTRO-CHEMISTRY.

APPLICATIONS.

- 2615 C. J. Hall and W. Lowrie, London. Improvements in absolutely continuous current dynamo-electric machines. February 23
- 2625 R. Harrison, London. Improvements in primary electric batteries. February 23
- 2631 J. Y. Johnson, London—Communicated by L. A. W. Desruelles, France. Improvements in electric batteries. February 23
- 2632 J. Y. Johnson, London—L. A. W. Desruelles. Improvements in the treatment and preparation of materials used in electric batteries. February 23
- 2647 L. N. Loeb, London—Communicated by J. H. Howard, United States. Improvements in galvanic batteries. February 23
- 2648 J. N. Loeb—J. H. Howard. Improvements in galvanic batteries. February 23
- 2704 A. Thompson and J. G. W. Fairbairn, London. Improvements in dynamo-electric machines. February 24
- 2773 A. M. Clark, London—Communicated by C. R. Goodwin, France. Improvements in voltaic batteries. February 25
- 2871 J. Musgrove—Musgrove, London. Improved apparatus or appliance for effecting the circulation of solutions in primary and secondary electrical batteries. February 27
- 2880 H. H. Lake, London—Communicated by G. E. Cabanellas, France. Improvements in and relating to apparatus for the generation and utilisation of electrical energy. February 27
- 2932 A. Schanschiff, London. Improvements in galvanic batteries. March 1
- 2956 M. Immisch, London. Improvements in electric motors and dynamo machines. March 2
- 2975 N. Tesla, London. Improvements in dynamo-electric machines. March 2
- 3183 T. A. Garrett, London. Improvements in and connected with dynamo-electric machines or motors. March 6
- 3235 C. J. Hall and W. Lowrie, London. Improvements in absolutely continuous current dynamo-electric machines. March 8
- 3253 H. H. Lake, London—Communicated by F. Heimel and F. Waldmann, Austria. Improvements relating to the conversion of electric currents, and to apparatus therefor. March 8
- 3475 R. E. B. Crompton, London. Improvements in dynamo electric machines. March 11
- 3476 A. Schanschiff and G. R. Fludder, London. Improvements in galvanic batteries. March 11
- 3554 W. Hartnell, Leeds. Improvements in dynamo electric machines. March 13
- 3577 A. C. Henderson, London—Communicated by E. Bazin, France. Improvements in the method of depolarising electric batteries. March 13
- 3605 J. Y. Johnson, London—Communicated by E. A. G. Street (otherwise Charles Street), and A. L. W. Desruelles, France. Improvements in means or apparatus for producing and regulating or controlling electric currents. March 13
- 3726 H. H. Lake, London—Communicated by J. Serson, United States. Improvements in galvanic batteries. Complete specification. March 16

COMPLETE SPECIFICATIONS ACCEPTED.

1881.

- 16437 J. S. Williams. Preparation and application of materials, etc., for the construction of electric apparatus cells, chambers or dielectrics. March 16
- 16438 J. S. Williams. Electric accumulators or batteries. March 16

1885.

- 2765 W. R. Lake—Communicated by A. Marchenay. Electrical accumulators or secondary batteries. February 26
- 6088 E. B. Burr. Galvanic batteries. March 5
- 8331 A. M. Clark—Communicated by C. R. Goodwin. An improved carbon element for galvanic batteries. March 12
- 13036 A. Bernstein. Carbons for incandescent lamps. March 23
- 15040 S. W. Maquay. Improved voltaic battery. March 19

1886.

- 1151 W. W. Popplewell—Communicated by F. La Otis Lathrop, J. W. Carter, and C. Fabre. Galvanic batteries. February 26
- 1160 W. P. Thompson—Communicated by A. H. Cowles. Smelting ores by electricity, and apparatus or furnaces therefor. March 23
- 1161 W. P. Thompson—Communicated by E. H. Cowles and A. H. Cowles. Lining for the walls of electric furnaces. February 26
- 1351 H. J. Allison—Communicated by E. M. Gardner. Electrode for secondary batteries. March 2
- 2403 H. J. Haddan—Communicated by E. H. Cowles and A. H. Cowles. Operating electric smelting furnaces. March 19

XIX.—PAPER, PASTEBOARD, ETC.

APPLICATIONS.

- 2656 O. W. G. Briggles, London—Communicated by Dr. J. F. Riep, Holland. Improvements in the treatment of reha and other fibres. February 23
- 2915 J. C. W. Stanley, London. Improvements in the preparation of materials suitable for being made into paper and for other purposes, and in apparatus therefor. March 1
- 3061 J. M. Walton, Manchester. Improvements in the construction and lining of boilers employed in the manufacture of paper-pulp from wood and other fibres. March 4
- 3111 H. Watson, Newcastle-on-Tyne. Improvements in strainer plates used in the manufacture of paper. Complete specification. March 5
- 3472 J. D. Tompkins, Nassau, United States. Improvements in process of making paper stock or pulp. Complete specification. March 11
- 3840 F. S. Reisenberger and M. C. Keith, London. An improved process for the manufacture of "half-stuff" for paper making. March 18

COMPLETE SPECIFICATIONS ACCEPTED.

1885.

- 5585 C. Weygong. Sizing paper and such like material. March 19
- 6839 R. C. Menzies, C. F. Cross, and E. J. Bevan. Preparation of paper-pulp from straw, esparto, wood, etc. March 19
- 7772 J. Petrie and F. W. Petrie. Machinery for cleansing "esparto" and other fibrous material used in making paper. March 16

1886.

- 2278 H. H. Lake—Communicated by C. E. Ball. Boilers or digesters for use in manufacturing paper-pulp. March 23

XXI.—EXPLOSIVES, MATCHES, ETC.

APPLICATIONS.

- 2692 D. L. Brain, London. Shell bursters for use with highly explosive agents. February 24
- 2715 G. F. Lutticke, London. An explosive projectile for toy cannons, guns, pistols, and the like. February 24
- 2716 E. G. Brewer, London—Communicated by L. Schoentjes and A. Jess, Germany. Improvements in or connected with fog signal apparatus. Complete specification. February 24
- 2974 F. W. Macan and W. J. Sharp, London. Improvements in the manner and means of attaching fuses to cartridges. March 2
- 3142 J. N. Heidmann, London. A new explosive compound. March 5
- 3313 E. Luck and A. Luck, London. Improvements in the manufacture of explosives. March 9
- 3399 C. W. Curtis and W. J. Brown, London. Improvements in the manufacture of gunpowder. March 10
- 3578 A. H. Burnford, London. Improvements in the manufacture of gunpowder. March 13
- 3593 O. Bowen, A. S. Tomkins, and J. Cobeldick, London. An improvement in the manufacture of gunpowder. March 13
- 3701 F. B. W. Roberts, R. Gansden, and A. Luck, London. Improvements in the manufacture of explosives. March 16
- 3901 W. Wells and C. F. Thompson, London. Improvements in fuzes for exploding shells, to be called "Wells's rotary needle sensitive fuze." March 19
- 3977 T. Birkett, Birmingham. A new or improved device for testing the force of guns, pistols, or powders of any kind. March 22

COMPLETE SPECIFICATIONS ACCEPTED.

1885.

- 5252 H. E. Newton—Communicated by A. Nobel. Explosive compounds. March 12
- 6517 W. Kennish. Explosive projectiles. March 12
- 6926 H. S. Maxim. Explosive compounds. March 23
- 7725 T. Smith. Safety dynamite shells, or shells loaded with other dangerous explosives. March 5
- 15129 E. Schultze. Manufacture of gunpowder and similar explosives. March 16

XXII.—GENERAL ANALYTICAL CHEMISTRY.

APPLICATIONS.

- 3170 E. Edwards, London—Communicated by P. Clair and J. B. Socard, France. An improved process for detecting fuchsine or other colouring matter of similar chemical composition in wine, vinegar, spirit, liquors, syrups, and other articles of the like kind. March 11
- 3591 S. A. Calderara and A. J. Calderara, London. An improvement in glass hydrometers. March 13

THE JOURNAL OF THE Society of Chemical Industry:

A MONTHLY RECORD
FOR ALL INTERESTED IN CHEMICAL MANUFACTURES.

No. 4.—VOL. V.

APRIL 29, 1886.

Non-Members 30/- per annum; Members
21/- per Set; Single Copies 2/6.

The Society of Chemical Industry.

Past Presidents:

Sir H. E. Roscoe, M.P., LL.D., V.P.R.S.	1881—1882.
Sir Frederick Abel, C.B., D.C.L., F.R.S.	1882—1883.
Walter Weldon, F.R.S.	1883—1884.
W. H. Perkin, Ph.D., F.R.S.	1884—1885.

COUNCIL FOR YEAR ENDING JULY, 1886.

President: E. K. Muspratt.

Vice-Presidents:

Sir F. A. Abel, C.B., D.C.L., F.R.S.	Peter Griess, Ph.D., F.R.S.
Sir J. Lowthian Bell, Bart., F.R.S.	W. H. Perkin, Ph.D., F.R.S.
Alexander M. Chance.	Sir H. E. Roscoe, M.P., F.R.S., LL.D., V.P.R.S.
Prof. James Dewar, F.R.S.	John Spiller.
James Duncan.	E. C. C. Stanford.
David Gamble.	J. C. Stevenson, M.P.

Ordinary Members of Council:

R. Forbes Carpenter.	S. A. Sadler, Ph.D.
Henry Doulton.	Sir Bernhard Samuelson, Bart., M.P.
John Evans, D.C.L., F.R.S.	Sir Chas. Tennant, Bart., M.P.
Ivan Levinstein.	Prof. W. A. Tilden, F.R.S.
Rudolph Messel, Ph.D.	John Williams.
B. E. R. Newlands.	
Thomas Royle.	

With Sixteen Chairmen and Secretaries of Sections.

Honorary Treasurer:

E. Rider Cook, M.P., East London Soapworks, Bow, E.

Honorary Foreign Secretary:

Ludwig Mond, 20, Avenue Road, Regent's Park, N.W.

General Secretary: Charles G. Cresswell.

Offices:

Palace Chambers, 9, Bridge Street, Westminster, S.W.

THE JOURNAL.

Publication Committee:

The President.

Sir F. A. Abel, F.R.S.	F. Hurter, Ph.D.
Joseph Bernays, M.I.C.E.	Ivan Levinstein.
W. Lant Carpenter.	Prof. R. Meldola, F.R.S.
Prof. Frank Clowes, D.Sc.	Ludwig Mond.
George E. Davis.	C. O'Sullivan, F.R.S.
Prof. Dewar, F.R.S.	John Pattinson.
Prof. Chas. Graham, D.Sc.	Dr. W. H. Perkin, F.R.S.
Peter Griess, Ph.D., F.R.S.	Sir H. E. Roscoe, M.P., F.R.S.
D. B. Hewitt, M.D.	John Spiller.
David Howard.	A. Norman Tate.
Prof. A. K. Huntington.	Thomas Tyrer.

Editor: Watson Smith, The Owens College, Manchester.

ASSISTED BY THE FOLLOWING STAFF OF

Abstractors:

G. H. Beckett.	A. R. Davis.
D. Bendix.	A. G. Green.
E. E. Berry.	S. Hamburger, Ph.D.
E. J. Bevan.	J. H. Hodgkinson.
W. Dalrymple Borland.	James Holme.
T. L. Briggs.	J. J. Hummel.
C. Claus.	Bertram Hunt.
E. G. Clayton.	C. C. Hutchinson.
Julius B. Cohen, Ph.D.	D. E. Jones.
C. F. Cross.	Herbert Jones.

Abstractors:

W. E. Kay.	H. A. Rademacher.
A. J. King, B.Sc.	F. W. Renaut.
D. A. Louis.	Samuel Rideal.
F. Machenhauer.	James Taylor, B.Sc.
Wm. Macnab, Jun.	F. L. Teed, D.Sc.
W. G. McMillan.	V. H. Veley, M.A.
G. Harris Morris, Ph.D.	Alex. Watt.
J. M. H. Munro, D.Sc.	Sydney Young, D.Sc.

NOTICES.

In accordance with the provisions of Rule 18 of the Bye-laws, notice is hereby given that those Members of Council whose names are placed in italics in the annexed list, will retire from their respective offices at the forthcoming Annual General Meeting.

Mr. David Howard has been nominated to the office of President, and Mr. E. K. Muspratt has been nominated Vice-president under Rule 11.

Sir H. E. Roscoe, M.P., has been nominated Vice-president under Rule 24; Dr. Ferdinand Hurter, Mr. John Williams, and Mr. Philip Worsley have been nominated Vice-presidents under Rule 8; and Mr. Eustace Carey has been nominated Ordinary Member of Council under Rule 17, in the place of Mr. John Williams, nominated Vice-president.

The Treasurer and Foreign Secretary have been nominated for re-election.

Members are hereby invited to nominate fit and proper persons to fill four vacancies among the Ordinary Members of Council under Rule 18. Special nomination forms for this purpose can be obtained from the General Secretary upon application.

Extract from Rule 18.—"No such nomination shall be valid unless it be signed by at least ten members of the Society, who are not in arrear with their subscriptions, nor unless it be received by the General Secretary, at the Society's Office, at least one month before the date of the commencement of the Annual General Meeting, to the election to take place at which it refers. Nor shall any such nomination be valid if the person nominated be ineligible for election under Rules 12 or 15. No member shall sign more than one nomination form."

ANNUAL GENERAL MEETING.

Members are hereby informed that the annual general meeting (1886) will take place in Liverpool on the 7th, 8th, and 9th of July. Details of arrangements will appear in due course. Tickets of membership will be issued in time for the meeting, and will form, as heretofore, vouchers for visits to works and excursions.

PROPOSED AMENDMENT OF BYE-LAWS.

Notice is hereby given, in accordance with Rule 54, that it will be proposed to the forthcoming Annual General Meeting to further amend the Society's Bye-laws as follows:—

Bye-law 1.—That the words "and is established in accordance with the provisions of the Literary and

Scientific Institutions Act, 1854," be added after the word "Industry."

Bye-law 5.—That the word "or" be inserted in the third line thereof between the words "Council" and "a professional."

Bye-law 27.—That the words "One Guinea" in the first line thereof, be replaced by the words "Twenty-five Shillings."

Bye-law 29.—That the words "is more than four months in arrear," in the second line thereof, be replaced by the words "has not been paid."

Bye-law 37.—That the word "President" in the second line thereof, be replaced by the word "Chairman."

Bye-law 42.—That the words "is in arrear with" be replaced by the words "has not paid."

Bye-law 49.—That the date "31st of December" be replaced by the date "15th of June."

Bye-law 54.—That the word "given" in the last line but one thereof, be replaced by the word "posted."

The supply of copies of the Journal for January, 1882, being now exhausted, the Secretary would be glad to receive communications from members possessing extra copies of that number, in good condition, with a view to purchase.

Should sufficient applications for complete sets be received, the number will be reprinted.

In reply to numerous inquiries, members are hereby informed that no tickets for the Colonial Exhibition have been supplied to the Secretary.

CHANGES OF ADDRESS.

Jno. Angus, 1/o Lime Street; Ingram House, 165, Fenchurch Street, London, E.C.

G. Beilby, 1/o Midealer; St. Kitts, Slateford, N.B.

E. Bramwell, 1/o St. Helens; Charlwood House, Hayton.

E. R. Budden, 1/o Ealing; "Camelot," Netherhall Terrace, South Hampstead, N.W.

C. Claus, 1/o Mark Lane; 24 Merton Road, South Wimbledon, S.W.

D. Clark, 1/o Glasgow; c/o Messrs. Tangyes, Limited, Cornwall Works, Birmingham.

E. C. Conrad, 1/o Wellesloe Square; 60 Sebert Road, Forest Gate, E.

Jno. Cox, 1/o Hunstanton; Cromwell House, Bexley Heath, Kent.

J. F. Davis, 1/o West 11th Street; 233, East 51st Street, New York, U.S.A.

H. Doidge, 1/o 19; 22, Alberta Terrace, Sherwood Rise, Nottingham.

G. Eschellmann, 1/o Mannheim; 8, Castle Street, Northwich, Cheshire.

A. Esilmann, 1/o Droylsden; North Road, Clayton, Manchester.

MEETINGS, SESSION 1885-86.—First Monday in each month (unless otherwise indicated).

ORDINARY MEETINGS.

First Monday in the Month, at 8 p.m.

May 3.—A. G. Salamon, A.R.S.M., F.C.S., and W. de Vere Mathew, F.I.C.—"The Purification of Water." Messrs. Macnab and Beckett—"The Treatment of Water for Technical Purposes."

June 7.—Dr. Meymott Tidy—"Chemical Treatment of Sewage."

July.—Annual Meeting at Liverpool.

Notices of papers and communications for the meetings to be sent to the Local Secretary.

Meeting held in the Lecture Theatre, Central Institution of the City and Guilds of London Institute, Exhibition Road, South Kensington, S.W., Monday, April 5, 1886.

DAVID HOWARD, ESQ., IN THE CHAIR.

THE TESTING OF PORTLAND CEMENTS.

BY PROF. W. C. UNWIN, M. INST. C.E.

ABOUT the year 1850 there was first produced a new cement, which from its resemblance to Portland stone when set, was called Portland cement. It has

the properties of setting rapidly and setting under water, and it slowly hardens to a condition in which it is nearly as strong as natural stone. In hardening, it has the very important quality of altering extremely little in volume. It rapidly established its superiority as a constructive material to Roman cement, and it bids fair, in spite of its greater cost, to largely supplant hydraulic lime. It can be kept with little deterioration and shipped to distant countries. Its use has extended till its manufacture has become one of the most important industries in this country, in Germany, in France, and in the United States.

Success in its manufacture depends on careful judgment and the rigid observance of essential conditions. It may be produced from a great variety of natural rocks, but broadly speaking, it consists of seventy-two per cent. of chalk and twenty-eight per cent. of clay.

Experience shows the exact proportion of the natural materials used which is most suitable. These materials must be so mixed that the cement is absolutely homogeneous and invariable in composition. At first, the chalk and clay were ground together with a large volume of water into a liquid slip. Now it is found that grinding with only thirty-five per cent. of water is not only economical, but prevents the segregation of materials which took place in fluid slip. With some materials no water is used in grinding. The mixed materials are then calcined to a clinker at a temperature just short of that which produces fusion. Underburnt clinker is weak, and overburnt clinker is an almost inert cement. Lastly, the clinker must be broken up and ground to a powder, so fine that the cement particles expose a maximum surface at which chemical actions may occur, and are not too large to fill the smallest inter-spaces in the sand with which the cement is mixed in use.

I must leave it to members of this Society more acquainted with chemical reactions than myself to decide on the nature of the hardening process, which gives its value to cement. Pettenkofer seems to make the process consist (1) in the formation of a silicate of lime and the hydration of the silicates of alumina and iron, (2) further in the reaction of the silicate of lime on the other silicates forming double hydrated silicates. According to Frey, there is (1) a formation of an aluminat of lime, and of hydrates which attain considerable hardness; (2) a reaction of the calcium hydrate on the basic calcium silicate. Experiment seems to show a progressive increase of combined water in hardening cement.

The primary guarantee of the goodness of a cement is, that it comes from a manufacturer who exercises the requisite care and who has appliances adequate for securing invariable quality in his product. But the enormous volume and cost of the cement used in engineering works has led to the adoption of special processes of testing, as a check on the manufacturer. In large works, like the Metropolitan Main Drainage, it was perceived that a considerable sum might economically be spent on systematic and regular tests of the quality of the cement supplied. A comparatively large sum spent in testing formed but a small percentage on the value of the cement, and as the quality of cement may vary through very wide limits, from qualities absolutely trustworthy to qualities absolutely dangerous, the cost of testing was fully repaid by the greater value of the cement obtained, and the thorough confidence with which after testing it could be used.

Testing began with comparatively crude tests of the tenacity of briquettes, or test pieces of neat cement, which at first were made of an excessively bad form, and were seldom tested after more than

seven days' hardening. It soon appeared that the form of these briquettes and the mode of making them greatly affected the apparent strength. Very insignificant differences in the quantity and temperature of the water used, and the time taken in ganging; in the pressure employed in moulding the briquettes, and so on, made differences in the apparent strength greater than the differences due to different qualities of cement. Diagram I. shows some of the forms used in testing for tenacity. The first form, Fig. 1, was excessively bad, the square corners producing unequal distribution of stress on the section. The most ordinary form is Fig. 5, which is simple to mould, and is held in clips, which embrace the specimen. A few engineers use forms like Fig. 7, in which the specimen is held between clips having a knife-edge passing through the enlarged end. There is probably something to be said for making the specimen longer than the common form shown in Fig. 5. The influence of the form of the briquette on the strength is considerable; different briquettes of the same cement, moulded in different forms, gave results at seven days, ranging from 280lb. per square inch for Fig. 1 to 460lb. per square inch for Fig. 5.

Gradually the proper form and the exact conditions for ganging briquettes of uniform quality have been determined by careful study, although it must be confessed that skill in ganging and moulding the briquettes still forms so large a factor in the results obtained, in the ordinary mode of testing, that it is difficult to get absolutely trustworthy comparative tests. Nevertheless, the chemical and physical properties present in the best cements have been ascertained. The manufacture has improved, and engineers now obtain cement of at least double the strength of that produced twenty years ago, and far more uniform and trustworthy.

The improvement of Portland cement, and the universal confidence now felt in its use, are due primarily to the experiments of Mr. Grant made between 1859—71, and communicated to the Institute of Civil Engineers in 1871. Since then many other engineers have made regular and scientific tests of large quantities of cement. But I believe undoubtedly the most careful, varied, and prolonged investigations have been made in the State Laboratories in Berlin and Munich. In this country cement testing has an exclusively commercial purpose in most cases. On the Continent the Government wisely provides means for researches, extending far beyond immediate requirements. The result has been a practical advance in the manufacture of a very marked kind.

I have here, for instance, a paper by Professor Bauschinger* of Munich, which indicates very remarkably the amount of care and labour devoted to investigations of this kind. Ten cements were tested. The weight, fineness, setting time, and chemical composition were first determined for each cement. Then mechanical tests on an unusually large scale were made. Test pieces were prepared and tested for four kinds of stress—crushing, tensile, transverse, and shearing. For each cement three series of test pieces were made—one set with neat cement, and two sets with one of cement to three of sand, and one of cement to five of sand. The tests were made for each of these sets, and for each of the four kinds of stress, both for test pieces hardened in air and hardened in water, and at periods of hardening of one, two, four, eight, sixteen, and 100 weeks.

The four tables of the results of these mechanical tests represent 7200 separate tests. In addition, there were tests of the ordinary small-sized test

* Mitth. aus dem mech. techn. Laboratorium der k. Hoehschule in Muenchen. 1879.

pieces, and subsidiary researches on the expansion of the cements after setting.

It may now be pointed out that there are two distinct objects in testing cement, involving to a certain extent quite different methods of procedure.

First, there is purely commercial testing, the object of which is to ascertain whether a cement satisfies contract conditions. In testing of this kind it is unfortunately unavoidable that the tests should be completed in a short time. To avoid freight expenses, the cement must generally be tested before it leaves the works at which it is manufactured. But as storage room is necessarily limited, a cement manufacturer cannot keep large volumes of cement for a period sufficient for perfectly adequate tests. Commercial testing has for the most part to be completed in a week, though at least a month is necessary for a really adequate test.

test, both fostered the production of coarsely ground and comparatively inferior cement. The great progress of the cement manufacture in Germany, and the production there of cements stronger in test and of more value in the market than English cements, is to be traced directly to the adoption of more rational tests.

In situ, a cement is hardly ever in tension, but ordinarily a tension test is adopted for determining its quality. It is never used neat, but always mixed with from three to twelve times its volume of the other substances, yet it is tested neat. It never is called on to resist stress till it has hardened for months; nevertheless, it is tested usually in seven days. Obviously the ordinary tests are empirical and may be misleading. Almost every circumstance which markedly affects the strength of a small briquette tested neat and soon after setting, produces a less effect on the

DIAGRAM I.

FIG. 1.

FIG. 2.

FIG. 3.

FIG. 4.

FIG. 5.

FIG. 6.

FIG. 7.

Second, there is scientific testing, the object of which is to afford information to the engineer. In this kind of testing, the conditions in which the cement is actually to be used must be imitated, and the tests must be extended over a not inconsiderable time.

Good commercial tests are those which enable us to detect with fair probability the qualities required by the engineer, so far as is possible in the restricted conditions in which such tests must be made. But they are necessarily imperfect, and just as a bad rule of tonnage measurement may directly tend to foster the production of bad and unseaworthy ships, so bad rules of commercial cement testing have contributed to hinder progress in cement manufacture. The brief neat cement tests, and the now obsolete weight

strength of a mass, mixed with other materials and tested after a longer interval of time. Hence, while it is impossible to alter the conditions of commercial testing, its empirical character requires to be steadily kept in mind, and its tendency to give an exaggerated estimate of differences in the cements tried. Further, the engineer is very unwise, if he does not, for his own satisfaction, carry out control experiments, larger in scale, more conformable to the conditions of use, and lasting a longer time than the tests which are necessary for contract purposes.

The constructional value of a building cement depends on two quite distinct elements—on its power of setting into a rigid form soon after it is gauged, and on its power of attaining in course of time a considerable strength. In the actual process of building,

especially building under water, it is important that the cement should set rapidly, and gain strength enough to keep its form. But, generally, it is only after the lapse of months, or even of years, that the structure is called on to exert its full strength. Hence any strength acquired by hardening during that time is advantageous.

Consequently, in judging of a cement from tests of its strength, both the initial strength acquired in a short time and the rate of gain of strength with age, require to be considered.

Now, suppose experiments have been made, say, at 7 days, 4 weeks, and 12 weeks. One would still like to be able to predict the strength at a greater age, and even in judging of the data in hand some difficulty arises from the discrepancies and anomalies incident to such experiments, and due to the difficulty of making the experiments numerous enough to get true average values. If anything were known of the

For all tension tests of Portland cement n may be taken as 1-3rd. For ordinary limes it has a larger value. For compression tests of comparatively large blocks of Portland cement n is 1-2nd. Consequently two tests of a cement at different ages determine the remaining constants of the formula.

If the equation is obtained from two such tests, the two constants indicate directly and simply the initial strength and rate of gain of strength with age, so that the equation may be termed the *characteristic equation* for the cement.

Further, if a series of tests at different ages are available, mean values of the constants can be obtained which give equal weight to all the results. The equation thus reconciles the anomalies which appear in all experiments of this kind. It virtually draws a smooth curve through the somewhat discordant results.

In applying the formula, I found very soon what

DIAGRAM II.

law of increase of strength with age, if we could put our results in a formula, their meaning would be much clearer.

Now the author has found that beyond the first week, and up to a period at which the full strength of the cement is reached, the rate of hardening follows very approximately a very simple law. For ordinary tension briquettes, for instance, the gain of strength is very nearly proportional to the cube root of the time of hardening, and that both for neat cement and cement mortar. It is possible, therefore, to represent the results of a series of tests in a simple formula, the constants of which indicate the character of the cement with very great clearness.

Let x be the number of weeks during which a test piece has been hardening. Then the strength y in lbs. per square inch at that age, is given very approximately by the equation—

$$y = a + b(x-1)^n$$

where a is the strength at 7 days, and b and n are constants depending on the rate of gain of strength with age.

does not appear so easily in tables of experiments, that neat cement briquettes generally reached their full strength in 3, or at most 4 months, while briquettes made with sand gained strength in a regular way up to 2 or 3 years at least. The formula, therefore, is only applicable within those limits of time.

The longest series of experiments with which I am acquainted is a series of experiments on briquettes of cement and cement mortar made by Mr. Grant, and extending over a period of 7 years. These experiments give the characteristic equations—

$$\text{Cement} \dots\dots\dots y = 363 + 48\sqrt[3]{x-1}$$

$$\text{Cement Mortar (1C+3S), } y = 157 + 40\sqrt[3]{x-1}.$$

Diagram II. shows these results for 3 years plotted with times as abscissa and strengths as ordinates. The experiments are shown by dots, and the strengths calculated by formula by the curves. The neat cement in this case gained in strength up to 104 weeks; the mortar briquettes probably longer, but beyond that time there was little or no gain.

The following table gives these results with the observed and calculated strengths :—

TESTS OF BRIQUETTES OF NEAT CEMENT, AND ONE CEMENT TO THREE SAND AT DIFFERENT AGES OF HARDENING (GRANT).

Age in Weeks.	Neat Cement. Strength in lbs. per sq. in.		1 Cement to 3 Sand. Strength in lbs. per sq. in.

312	580	—	364	—
364	590	—	383	—

Fineness of Grinding.—The greater part of the improvement in the quality of cement, which has been effected in the last ten years, has been due to the discovery of the importance of grinding the clinker to extreme fineness. The amount of surface the par-

If cement is taken and sifted through a sieve of 50 meshes to the inch, the residue on the sieve of particles larger than the holes in the sieve will not adhere together sufficiently to form a briquette. They are almost absolutely without cementitious value. But if these same particles are reground they are converted into valuable cement.

The extremely small value of these larger particles in the cement was not for some time perceived. For a long time all tests of the strength of cement, or nearly all, were made with neat cement, the reason being that tests of this kind can be made more rapidly than any others. Now, a good cement will bear the addition of a certain amount of inert matter without any sensible reduction of strength; indeed, with a certain gain. Hence it happens that in neat cement tests a somewhat coarsely ground cement gives results higher than a finely ground one. But cement is never, in fact, used neat; it is used mixed with three to seven or more times its weight of the cheaper material, sand or gravel. In the German laboratories, therefore, it was thought desirable not to test the cement neat, but to test it in the condition in which it is used in practice, mixed with sand; and directly this was done, it was found that the cements which were strongest tested neat were by no means always strongest tested as mortar mixed with sand. There may be more reasons for this than one, but the principal reason is that the more finely ground cement will bear a considerable addition of sand with less loss of strength than the coarsely ground cement. The coarse cement has, in fact, a proportion of matter as inert as sand already mixed with it.

Suppose a cement has 10 per cent. of inert matter;

DIAGRAM III.

60% FINE.

BARREL OF CEMENT.

90% FINE.

ticles of cement expose, increases inversely as the diameter of the particles. A cubic inch of cement would have 150 sq. ins. of surface, if the particles were spherical and $\frac{1}{25}$ th inch in diameter, and 600 sq. ins. if they were $\frac{1}{100}$ th inch in diameter; so that the area on which chemical action occurs increases as the cement is ground more finely. But probably this is only part of the explanation of the greater value of very finely ground cement.

then, when mixed with sand in the proportion of 2:1, the true ratio of cement to inert matter is 1 to 2.33; but if the cement initially contains 40 per cent. of inert matter, then, when mixed with double its weight of sand, the true ratio of cement to inert matter is 1:4.

Diagram III. shows two barrels of cement, one containing 10 per cent. and the other 40 per cent. of particles, so coarse that they are practically of no more

value than sand. The difference of commercial value of the two cements is very easily seen. Since the coarse particles can be converted into good cement by grinding, the importance of fine grinding in developing the value of the cement is easily seen.

The Germans were the first to use the sand-mortar test instead of the neat cement test, and it has been

A series of experiments given in Mr. Elliot Clarke's very interesting "Report on the Boston Main Drainage Works" shows the effect of fineness of grinding still more strikingly. An English Portland cement was taken and divided into portions, which passed through a 50, 70, 100, and 120 sieve. Briquettes made with these and with different proportions of sand were

DIAGRAM IV.—FINENESS OF GRINDING (Grant).

directly due to this that they attach greater importance to fine grinding than English manufacturers. Improvement in England has gone on the same direction as in Germany, but it has not yet proceeded so far.

The best German cements are so ground as to leave a residue of only 3 to 10 per cent. on a 76-mesh (per inch) sieve. English cements, even well ground, leave 10 per cent. on a 50-mesh sieve.

Diagram IV. shows the results of a series of tests by Messrs. Dyckerhoff, given in Mr. Grant's paper. The same cement was used in all the tests; but in one series the cement was used as manufactured, in the other after sifting through a fine sieve. The former left 10 per cent. on a 50-mesh sieve; the latter all passed through a 180-mesh sieve.

The equations corresponding to the curves in the diagram are as follows:—

Neat cement.

Neat unsifted cement—

$$y = 353 + 122\sqrt{x-1}$$

Neat sifted cement—

$$y = 346 + 36\sqrt{x-1}$$

1 Cement + 3 sand.

Cement unsifted—

$$y = 75 + 69\sqrt{x-1}$$

Cement sifted—

$$y = 252 + 53\sqrt{x-1}$$

1 Cement + 5 sand.

Cement unsifted—

$$y = 31 + 46\sqrt{x-1}$$

Cement sifted—

$$y = 136 + 47\sqrt{x-1}$$

tested at different periods, from one week to 52 weeks. The following equations give the results:—

EFFECT OF FINENESS OF GRINDING (Boston).

Percentage which would not pass through a 100 sieve.	1 Cement + 3 Sand.	1 Cement + 5 Sand.
55	$y = 39 + 28\sqrt{x-1}$	$y = 19 + 10\sqrt{x-1}$
33	92 + 42	43 + 32
23	97 + 45	47 + 35
18	117 + 44	65 + 35
8	123 + 50	73 + 36
0	154 + 41	86 + 35

Heaviness of Cement.—It was early discovered that heavy, well-burnt clinker produced better cement than the lighter under-burnt clinker. Hence for a long time it was prescribed in all specifications that the cement should have a certain weight per bushel.

To get uniform results the cement is sifted through a very coarse sieve, and allowed to fall through a funnel three feet high into the standard measure. The cement is strickled off, and the measure weighed without shaking. The size of the measure must be defined, as the cement packs closer in a large than in a small measure. Bauschinger found 13 per cent. difference between the weight of cement in a 50-litre and a 1-litre vessel. But another influence affects the result. A cement ground coarsely will give a heavier weight

than the same cement ground finely, so that the weight-test is a premium on coarse grinding. Since this has been understood, the weight-test has been generally abandoned.

The weight per cubic foot of the same cement of different degrees of fineness was determined at Boston, with the following results:—

Per cent. retained on 120 sieve.	Weight per cubic foot.
0	75
10	79
20	82
30	86
40	90

Diagram V. shows these results plotted in a curve. It is still, however, convenient to know the weight per cubic foot, and if the fineness is taken into account it affords some indication of the quality.

PER CENT
LEFT ON
120 SIEVE.

DIAGRAM V.

Influence of the kind of Sand used in making Cement-mortars.—The sand used with cement in making mortar is commonly directed to be clean, sharp, silicious sand. It is usually specially directed that the sand should be free from clay. Experiment seems to show that a percentage of clay does not really harm the cement. But leaving this question aside, and supposing we have got a clean siliceous sand, tests will give very different results, according to the quality of the sand. For instance, experiments given by Mr. Grant with Berlin standard sand and a coarser sand give the following equations:—

Standard Berlin sand. Briquettes pressed—

$$y = 73 + 31\sqrt[3]{x-1}$$

Standard sand. Briquettes not pressed—

$$y = 89 + 19\sqrt[3]{x-1}$$

Coarser sand—

$$y = 172 + 28\sqrt[3]{x-1}$$

These experiments extended over a year. The experiments are plotted in Diagram VI.

Diagram VII. shows some experiments on a Portland and American (Rosendale) cement, made with a sand unsifted (marked *mixed* on the diagram), and on

portions of the same sand of different degrees of fineness obtained by sifting. It will be seen that the coarser sands give briquettes of greater strength; but the unsifted sand is nearly as strong as the coarsest. For use on works the mixed sand would be good, but for comparative experiments sand of a definite size is preferable.

By coarseness of the sand we mean, primarily, size of grain. Large-sized sand is good for exactly the inverse reason that fine cement is good. Fine cement coats a large surface, and fits well into the interspaces of the sand. Large-grained sand has less surface to coat, and its spaces are more easily filled with cement. Now, uniform size of grain may be obtained by sifting. Standard Berlin sand passes through a 20- and is retained by a 28-mesh sieve. But sands of uniform size of grain do not make equally good mortar. Two sands

sifted through and retained on the same sieves give different tests. There is something in the form of the grains and the kind of space between them—possibly even something in the chemical condition of the sand—which affects the initial strength and rate of hardening of the briquette. These different qualities are shown very clearly in the following characteristic equations, deduced from experiments by Mr. Arnold, at the Harbour Works at Willemshaven. The tests are 1 cement to 3 sand—the same cement used throughout.

Willemshaven blue sand—fine-grained and sharp—

$$y = 101 + 22\sqrt[3]{x-1}$$

Dangast normal sand, sifted in the same way as Berlin normal sand—not very sharp—

$$y = 124 + 23\sqrt[3]{x-1}$$

Dangast common building sand—

$$y = 165 + 13\sqrt[3]{x-1}$$

Wangeroog, coarser—clean and sharp—

$$y = 193 + 41\sqrt[3]{x-1}$$

Berlin normal, clean sharp quartz sand—

$$y = 250 + 44\sqrt[3]{x-1}$$

Influence of Proportion of Sand on the Strength of the Mortar.—Cement mortars are weaker than neat cement, probably because the adhesion of the cement

1 cement to 3 sand, the whole of the interstices of the sand cannot be filled with cement, and as the proportion of sand increases the proportion of unfilled space

DIAGRAM VII.

to the sand is less than the tenacity of the cement. The larger the proportion of the sand the weaker the mortar. It appears that even with a proportion of must increase, and therefore there must be a less section to break.

From a series of tests, by Mr. Elliot Clarke, of

about 500 briquettes, all made with the same cement (the tests extending over two years), I get the following very uniform series of equations :—

PORTLAND CEMENT MORTAR, WITH DIFFERENT PROPORTIONS OF SAND (Boston).

Neat Cement	$y = 303 + 61\sqrt[3]{x} - 1$
1 Cement+1 Sand	160+57 ..
1 .. +2 ..	126+41 ..
1 .. +3 ..	95+36 ..
1 .. +5 ..	55+26 ..

Below are given the results of experiments by Dr. Böhme on the influence of the addition of various substances to cement. Some of these, such as gypsum, have been added at times with an idea that they improved the cement; others have been added occasionally as adulterations. Slacked lime has occasionally been used with cement in very cold weather. It will be seen that, with the exception of sifted cement, every one of these additions reduces the strength of the cement :—

VARIOUS ADDITIONS (Böhme).

(A, Cement; B, Sifted cement; C, Fine sand; D, Slag; E, Brick-dust; F, Slack-lime.)

MIXTURE.	Neat.	1 Cement to 3 Sand.
100 A	$y = 583 + 88\sqrt[3]{x} - 1$	$y = 199 + 18\sqrt[3]{x} - 1$
90 A+10 B	498+93	213+45
90 A+10 C	526+69	128+65
90 A+10 D	469+77	128+59
90 A+10 E	452+107	137+58
90 A+10 F	514+71	155+48
50 A+50 F	262+88	82+44

Effect of Time of Setting on the Qualities of a Cement.—There is a prevalent opinion that quick-setting cements do not continue long to gain in strength, but reach a maximum, and then fall off, or diminish in strength. This curious diminution in strength, often shown in experiments, may be due to minute and imperceptible cracks, but I am a little inclined to think that it is rather an error of testing than a real loss of strength. The cement, no doubt, gets more brittle, and that has the effect of making the test more difficult, and increasing the chance of breaking the briquette with a load rather less than the real tenacity.

Mr. Grant has given a table of tests of quick and slow cements, from which I have deduced the following characteristic equations. Mr. Grant does not say, but I believe these are 28-day tests of mortar gauged 1 to 3 of sand :—

Set in Minutes	Quick Cements.	Set in Hours.	Slow Cements.
10	$y = 7 + 95\sqrt[3]{x} - 1$	5	$y = 166 + 80\sqrt[3]{x} - 1$
20	34+113	7	101+94
30	83+86	10	113+70
45	23+90	11	140+67

These results show that the slower cements have very much greater initial strength than the quick cements, but I think the quick cements in this table

are somewhat exceptional. Taking the means of four series of tests on quick cements and four on slow cements from Bauschinger's tables, I get the following equations :—

	Quick Cements.	Slow Cements.
Gauged neat.....	$y = 183 + 18\sqrt[3]{x} - 1$	$y = 220 + 55\sqrt[3]{x} - 1$
1 Cement to 3 Sand	$y = 76 + 36\sqrt[3]{x} - 1$	$y = 88 + 47\sqrt[3]{x} - 1$

Here the slow cements have greater initial strength and greater rate of gain with age than the quick cements, but the difference is not so great as in Grant's table. At any rate, the opinion is general that the slower cements are more trustworthy. The German manufacturers propose different standard tests for quick and slow cements, the standard being higher for the slow cements.

Influence of Quantity of Water on the Strength of Neat Cement and Cement Mortar.—A certain quantity of water must be used in gauging cement or cement mortar, which varies with the character of the cement. The finest ground and quickest cements require most water. Now, unfortunately, every drop of water added beyond what is necessary weakens the cement, and this is the chief source of the discrepancies which occur in cement testing. In purely commercial testing, it is naturally and not unfairly desired to get the best result possible out of the cement. In this country the briquettes are moulded on an impervious slab of slate or marble or glass. The cement is gauged neat with the least amount of water which will permit moulding, and the very stiff paste into which the cement is formed is pressed into the moulds as rapidly as possible. To get uniform results, the water used must be very accurately measured. It varies from 18 to 25 per cent. of the weight of cement.

In Diagram VIII. are shown the results of some experiments at Boston, on the same cement, mixed with different proportions of water. The greatest strength is obtained with between 20 and 25 per cent. of water. The proportionate difference of strength as the time of hardening increases is less, so that it is for short, one week tests, that the quantity of water makes the greatest difference.

In Germany it has been found that if an absorbent block of gypsum is used under the briquettes in moulding, 5 per cent. more water may be used, and more uniform results obtained. Although the gypsum block is hardly ever used in this country, I think it is a distinct advantage that it permits us to gauge the cement to a condition in which it can be poured into the moulds without pressure. But in Germany the sand and cement, or cement mortar test, is almost always used, and in this test the quantity of water used does not influence the strength so largely as in the neat cement test.

The sand or mortar test has other advantages. It corresponds more closely to the conditions in which the cement is actually used, and in plotting the results of experiments I have always found that sand tests plotted in smoother curves than neat cement tests. Against these advantages the cement and sand test has one drawback, which almost precludes its use in ordinary commercial testing, and that is that the cement mortar hardens more slowly than neat cement, so that 28 days at least should be allowed for the test. But if a neat cement test is adopted for contract purposes, the engineer should make cement and sand tests for his own information.

Test for Soundness.—One of the most dangerous qualities of a cement is a tendency to blow or crack after setting, in consequence of expansion due to the

chemical actions which are going on. Expansion of this kind producing cracks is commonly due to the presence of unslacked lime in the cement; gypsum added as an adulteration is open to the same objection. These substances are the more dangerous that they rather add to than detract from the strength of the cement, and hence escape detection by the ordinary test.

That Portland cement does expand in hardening may be shown easily by filling lamp glass chimnies with the cement, and placing them for hardening in water. This was done at the Boston sewerage works. With both neat cement and cement and sand, the chimnies invariably began to crack about the third day, and in the course of 10 days the glass cracked all over. Some glasses cracked in this way are placed on the table.

Measurement of Expansion of Cement.—Bauschinger took cubes of cement of 4.8 inches length of side. Twenty-four hours after mixing, a small brass plate, about $\frac{1}{16}$ -inch diameter, was fixed into two opposite sides of the cube, by cementing. After 48 hours' hardening, the accurate measurements between the brass plates were commenced. The cube was placed in a measuring instrument, having a spring touch lever on one side and a micrometer screw on the other. The touch lever ensured the constancy of pressure between the measuring points and the block to be measured. The pitch of the screw was very accurately determined, and as a perfectly constant temperature cannot be insured in experiments lasting a long time, a correction for the expansion of the cement blocks by heat was determined.

The ordinary test for soundness is to make a pat or cake, two or three inches in diameter, and half-an-inch thick, with thin edges, and place it in water. If the cake, in hardening, shows any tendency to crack or contort, the cement is dangerous.

It is often extremely important to determine the soundness of a cement in a shorter time than this process requires. Now, heat accelerates greatly the hardening process, and hence sometimes the pats of cement are placed on an iron plate heated by a gas jet. Then any tendency to crack shows itself in a short time. This may be called the baking process.

A still better process is to heat the pats in a steam bath. Mr. Faija makes a convenient apparatus, consisting of a double bath with regulated gas jet. The water in the outer bath is kept at 110°, and the pats placed in the steam on a slip of glass, in the inner bath, are in vapour at about 100°. After 5 or 6 hours the pat is hard enough to be placed in the water, and may be kept cooking for 20 hours. If at the end of that time the pat is still adherent to the glass, and without cracks, the cement is perfectly sound.

Neat cement briquettes hardened in air sometimes showed a small expansion at first, but all ultimately shrunk in volume. Neat cement briquettes hardened in water all showed a very small expansion, generally less than .05 in. in 120 mm. length in 16 weeks. With briquettes mixed with sand the changes of volume were of the same kind, but smaller.

Quickness of Loading.—I believe Mr. Faija first pointed out that the rate of loading a briquette affected the breaking weight. The quicker a briquette is loaded the greater the load which can be got on before it gives way. In some definite experiments, Mr. Faija found a difference of 23 per cent. in the breaking weight of exactly similar briquettes, broken quickly and broken slowly. It is now generally recommended that the weight should be added at the rate of 100 lbs. in 15 seconds. Mr. Adie has devised an ingenious arrangement for regulating the speed of loading. Mr. Deacon, I believe, puts half the probable breaking weight on the briquette, and leaves it 12 hours, and then completes the test.

Tests by Compression.—Almost all that has been said thus far relates to the ordinary mode of testing

cements and cement mortars by tensile stress. That mode of testing was adopted for mere reasons of convenience. The cement has only about one-tenth the strength in tension which it has in compression. Hence, for tension tests a small, cheap, easily managed testing machine can be used. For compression tests, the testing machines must be much larger and more costly. But as a matter of fact cement is but little used in positions in which its resistance to tension is in play. The most important works in which cement is used are expressly designed to avoid tension in any part. If, indeed, in some positions structures are exposed to the possibility of tensile strains due to failure of foundations or backing, still the tensile stresses so developed are small compared with the normal crushing stresses for which the structure is designed.

Tension tests having been adopted, and being convenient, no doubt, find defenders. Broadly speaking a cement with high tenacity will be strong to resist crushing; but the correspondence in the resistance to the two kinds of stress is far from exact. Bauschinger has found that the ratio of resistance to crushing to resistance to tension varies from 11 to 1 to 7 to 1, and that the order of merit for cements tried for tension is not the same as the order for crushing. It has even been said that crushing tests are useless and inaccurate. If they have proved so, it is only because the proper conditions of accurate testing have been neglected. In Bauschinger's tests of 5-inch cubes, the results are considerably more uniform than the tests of the same cements in small briquettes by tension.

In proper crushing experiments two conditions must be fulfilled, which have hitherto been too much neglected in crushing experiments. (1.) The faces of the block on which the crushing pressure acts must be plane parallel surfaces. (2.) The crushing pressure must be uniformly distributed on those surfaces.

In moulded blocks of cement or cement concrete the surfaces are hardly ever as parallel as is desirable. The surfaces are generally more or less rough, and more or less warped. I have found a very convenient and simple way of getting over this difficulty. By striking over the faces a thin layer of gypsum or parian cement, which sets immediately, perfectly plane and parallel faces can be obtained without in any way altering the strength of the block. Weak as these cements are, thin layers stand the crushing pressure perfectly.

To ensure the equal distribution of the crushing pressure on the faces it is only necessary, in a properly constructed testing machine, to interpose a spherical joint between the block and the face of the machine.

I have on the table some large blocks (9-inch cubes) crushed in this way.

Detection of Adulteration.—The means of detecting adulteration of cement have been examined by Drs. R. & W. Fresenius. Adulteration by lime is shown by too low a specific gravity, great loss by ignition, high alkalinity of aqueous solution, and too great absorption of carbonic anhydride. An adulteration by slag is shown by slightly lowered specific gravity, lowered alkalinity, and by the large amount of chameleon solution which may be added. The details of the methods of testing are given in a paper abstracted recently for the Institute of Civil Engineers.*

I have now only to thank you for the attention you have given to this lecture, and sum up the general drift of the lecture in a conclusion which has already been urged with much force by Prof. Bauschinger. No other experimenter has had greater experience, or

has carried into the work of mechanical testing greater scientific knowledge. For ordinary testing of cement the ordinary methods must suffice. They serve their purpose well, they cost little, and in the time available for such tests they are the best to adopt. But for the full determination of the relative value of different cements, for the determination of the resistance of cement in the conditions in which it is actually used, experiments on a larger scale, with more costly apparatus, and extending over a longer interval of time, have now become necessary.

DISCUSSION.

The CHAIRMAN, in inviting discussion, said they had to thank Professor Unwin for a paper which, although not strictly on chemical lines, was a very useful paper, which showed the necessity they all felt for physical methods of investigation as applied to many practical operations which they had to carry on.

Mr. MUMFORD said he had had occasion to make some experiments with cement in clinker, and it appeared to him that when ground down into cement it was necessary that it should be of the same chemical composition as the clinker, and it occurred to him that the diagram showing the weight per cubic foot required some further explanation. Seeing the different weight per cubic foot of cement according to the fineness of grinding, it appeared to him that probably the coarser portion which was left behind on the sieve consisted of the harder constituents of the clinker, and were probably of different chemical composition, and probably contained more silicious matter. He had passed cement through a machine which gradually reduced the clinker to powder, and he found on eliminating the fine from the coarse in the first process he got a very large proportion of lime and a small proportion of silica, and he then took that part which would not pass through the sieve, reduced that to the same degree of fineness as that which came off in the first operation, and then thoroughly intermixed the two, and having sent them to a cement manufacturer who submitted them to very severe tests, he found that that which came off first—the softer portion, as he considered—would bear scarcely any strain. The more silicious particles when reduced to powder would bear a little more strain, but when a mixture of the two was formed, a very good cement was made. He should like to know if cement which weighed seventy-five pounds to the cubic foot would bear the same strain, and was of the same composition as that which weighed ninety pounds?

A MEMBER said he had long acquaintance with Portland cement, which at one time was not considered genuine unless it had a "blue" shade. Other and wiser tests were happily now applied and requisite. He was curious to know whether the common salt which was in the Medway mud was an essential constituent? If so, was salt used in any proportion in the production of cement from materials inland?

Mr. W. CROWDER said he had purchased considerable quantities of cement, and for want of better he applied the sieve test. He quite agreed that cement should be as finely ground as possible, since the coarse particles of genuine cement practically acted as so much sand and were diluents. He would be glad to know what was the standard sieve for cement, but since machinery had now been so much improved, he saw no reason why the 100-mesh sieve should not be taken as a standard.

Mr. A. E. FLETCHER thought the value of the principle of examination or testing had, in the case of cements, been eminently useful. By the use of the machine before them, contractors had a reliable test.

He asked if the expansion of cements varied according to the proportions of sand and cement?

Mr. BERNAYS said he had had a little experience in the use of cement, and could appreciate the difficulty on applying a proper amount of water. In testing small briquettes one inch square, he found after a month some of the ordinary modern cements bore over 600 pounds per square inch, but that was only after they had got some experience as to the proper amount of water. At first they used thirty per cent., and could not get it to set at all; the briquettes would lie sometimes a week without getting hard, but by gradually reducing the water to about twenty per cent. they found they had an excellent cement. They were using one of Mr. P. Adie's machines, which was exceedingly ingenious and simple, and gave a good result; the only difficulty he found was at the point where the two hooks grasped the briquette; unless they were very carefully centered and kept vertical the result varied very much. If some alteration could be made in the machine in that respect it would be an advantage. At present you might have two briquettes taken from the same mould on the same day, one bearing, perhaps, 200 pounds more pressure than the other, simply from the difference in the mode of grasping. The question raised by Mr. Mumford seemed a very pertinent one, and he had no doubt the difference in the strength of cement when sifted and unsifted had something to do with its chemical character, as well as with the mere size of the grains. He could quite understand that in grinding, the hard particles being at the same time chemically different would be less affected than the soft ones, and remaining behind on the sieve the chemical composition of the cement under test was altered. After cement had been passed through the sieve, the coarse particles should be re-ground and mixed with the rest.

Mr. WALLACE (Glasgow) said he had occasion to make a number of tests of Portland cement, sent to him to find out why they were defective. He had invariably found that analysis led to very little if any result, but when he sifted them the discovery was made that in all the bad samples there was too large a proportion of coarse particles. His experience agreed with that of Mr. Lees of the Clyde Navigation, who had used many thousands of tons, and tested it regularly. The average cement should not contain more than fifteen per cent. which would not pass through a 60-mesh sieve, and seventy per cent. of it should pass through a sieve of 90 meshes to the inch. His experience was simply this, that chemical analysis was of little use, but that sieving and practical tests such as those which had been referred to were those which should be made. The testing of neat cement was of little value, because cement was never so used practically. With regard to sand, there was no doubt that practice had pointed out that coarse sharp sand was the best, simply because there was a less extent of surface to cover. The reason why Portland cement so rapidly supplanted Roman was because it set so much slower, and so gave time for a thorough mixing of the water and sand. The Portland cement improved in quality the older it became. The previous speaker had anticipated a question which he was going to put, whether the experiments in the glass cylinder were made with neat cement, or cement and sand? Because, of course, sand had a marked effect in diminishing the expansion.

Professor UNWIN, in reply, said the first point raised was whether the apparent variation of density was due to segregation of the materials by sifting? To a limited extent that might be so, and his own impression was that probably the harder and better

burnt clinkers chiefly made the coarser particles, and to that cause part of the variation would be due; but there was a much greater variation of density than could be explained in that way, and it was mainly due to mere difference of packing. The other point raised was as to the expansion of Portland cement. Until lately the real facts had not been at all known, and they were only now known through some exceedingly delicate and beautiful measurements by Bausehinger. He had found that all good Portland cements hardened under water slightly expanded, and they expanded more when gauged neat and not mixed with sand. The expansion went on for a long time, but was extremely small, .05 of a millimetre in 120 millimetres as a maximum. It was only by some rather delicate test like the lamp glasses exhibited that this expansion could be made obvious.

NOTE ON SO-CALLED "PANCLASTITE."

BY H. SPRENGEL, PH.D., F.R.S.

IN "Notice sur la Panclastite, etc., 'par' Eugène Turpin, Paris, E. Bernard & Cie., 1882," we read:—

P. 11.—"PANCLASTITE. (Brise tout :—de : *παν*, tout; *κλαω*, je brise.) Explosifs à base de peroxyde d'azote.

"Principe découvert par Eug. Turpin (1878 à 1882).

"Le corps comburant est le peroxyde d'azote pur et anhydre à l'état liquide.

"Cette section a cela de tout à fait remarquable, c'est qu'aucun des produits qui entrent dans la composition des nombreux explosifs qui en font partie n'a jamais été employé à la confection d'un autre mélange détonant. Le comburant ou les combustibles n'ont jamais été appliqués, en aucun cas, dans ce but, soit ensemble, soit séparément, tandis que dans les 1re, 2e et 4e sections on retrouve le soufre et le charbon.

"Recherchant de suite toute ce que pouvait lui donner la découverte de ce nouveau principe, M. Turpin est parvenu à produire plus de cent explosifs nouveaux, c'est-à-dire un nombre plus considérable que celui qui comprend tous les explosifs connus antérieurement."

P. 5.—"La Panclastite est dans ce dernier cas. Découverte par M. Eugène Turpin, elle constitue une invention de principe qu'il ne faut pas confondre avec une invention reposant sur des principes connus, ce qui est le cas de la dynamite; les inventions de principe sont extrêmement rares et tendent à diminuer encore au fur et à mesure que le progrès se développe, tandis que les inventions d'application ou de perfectionnement augmentent constamment."

On this "invention de principe" Sir Frederiek Abel, in his Presidential Address at the annual meeting of the Society of Chemical Industry, July 11, 1883 (vol. ii. p. 313), kindly expresses himself thus:—

"Sprengel urged that the facts brought forward by him were susceptible of important application, because powerful explosive cartridges or charges might at any time be rapidly prepared from two ingredients which, kept separately, are non-explosive. The suggestion to deal, in mining or military operations, with highly-corrosive and more or less volatile liquids, upon the extensive scale which would be necessary if Sprengel's system were turned to practical account, has not commended itself to those experienced in such matters; but attention has quite recently been directed to the subject by a M. Eugène Turpin, who puts forward as an invention of his own what he calls a new series of explosives, which he has christened 'Panclastite,' but which are actually Sprengel's explosive mixtures. In his memoir of 1873, Sprengel gives a table of the total percentages of oxygen, and the percentages of available oxygen, in a great number of oxidising agents, and the superiority of monohydrate of nitric acid over the majority in the

latter respect is there shown. Turpin uses, or says he uses, anhydrous nitrogen peroxide as the oxidising agent in his Panclastite series, together with carbon bisulphite or nitro products of hydrocarbons. He therefore carries out Sprengel's suggestions, selecting for the purpose an oxidising agent of comparatively costly and inconvenient nature, and certainly not superior in oxidising power to the strongest commercial nitric acid. The publication in France of researches or inventions as original, the results or description of which have long been published in England, is an occurrence to which we are not unaccustomed, and so the performances of Sprengel's offspring, furnished by M. Turpin with an impressive family name, are exhibited at Chatou-Rueil, near Saint Germain, with much flourish of trumpets, and have recently been officially reported upon by a Royal Engineer officer as marvels of novelty and of explosive power."

Though it may appear to be somewhat late to refer at this time to the foregoing comments on my paper in the *Journal of the Chemical Society* of August, 1873, I hope that the importance which this matter promises to attain will excuse and justify the following note:—

Note.—The "bean idéal" of a detonating explosive is a mixture of 8 parts (88.9 per cent.) of liquid oxygen and 1 part (11.1 per cent.) of liquid hydrogen.

In my paper of 1873 I say (page 799):—"On referring to the foregoing table the reader will be reminded that peroxide of hydrogen is the highest oxygen compound known, while nitric anhydride is the compound which contains the largest amount of oxygen available for combustion (74 per cent.). But as this compound, as well as the next two, nitric peroxide (69.5 per cent. oxygen) and tetranitromethane (65.3 per cent. oxygen) are, at present, on account of their nature and their difficult preparation, mere chemical curiosities, my attention naturally turned to the fourth, to *nitric acid* (63.5 per cent. oxygen), which is a cheap and common article of commerce."

Now, when M. Turpin's attention turned to the second oxidiser on my list—to nitric peroxide—he found that this substance does *not corrode* metals, such as iron, copper, and tin under 356° F. (180° C.); and further, that combustible liquids, such as petroleum, carbon bisulphide, and nitrobenzene are readily soluble in nitric peroxide *without* rise of temperature. These are valuable properties, *first noticed by M. Turpin*.

What was formerly a chemical curiosity is now an article of commerce. Nitric peroxide may be bought to-day at eighteen-pence the pound, and I see ways and means of producing it a great deal more cheaply. Nitric peroxide is a yellowish liquid, heavier than water (sp. gr.=1.451) and boils at 71° F. (22° C.), but may be kept like ether or similar volatile liquids. In France it is sent about in tinned-iron cans.

Taking as a typical example a benzene mixture

we see that the 18.4 parts of benzene require 56.8 parts of oxygen for the oxidation of their carbon and hydrogen to carbonic acid and water. This oxidation or combustion takes place at the moment of explosion at the expense of the 56.8 parts of oxygen contained in the rest of the mixture—the 81.6 parts of nitric peroxide. No other explosive now in use (including blasting gelatin) contains weight for weight a greater amount of combustible matter, and as an explosion of *these* bodies is simply a sudden combustion, I again beg to draw attention to the fact

that the oxygen available for combustion in gun-cotton is most probably not more than 32.3 per cent., and in nitro-glycerin 42.3 per cent.,* while in this case we have, without a doubt, 56.8 per cent. Hence no other explosive now in use can rival this and similar mixtures in power, as I published in 1873. They still remain *the most powerful* explosives known.

It hardly need be said that an explosive of this nature consists of two parts—an oxidising and a combustible agent,—and that M. Turpin with the same *naïveté* lays claim not only to the first, but also to the latter half of the subject.

None of my *safety*-explosives are licensed in England, though many of them, when mixed, are much less sensitive to concussion than common gunpowder.

THE PRESIDENT IN THE CHAIR.

COTTON-SEED OIL: ITS COLOURING MATTER AND MUCILAGE, AND DESCRIPTION OF A NEW METHOD OF RECOVERING THE LOSS OCCURRING IN THE REFINING PROCESS.

BY JAMES LONGMORE.

THE uses of cotton seed form a rapidly increasing industry, and the imports into the United Kingdom in 1885 reached 275,000 tons. The manufacture in the United States is probably ten times that amount, and considerable quantities are crushed on the Continent.

The oil expressed from the seed, when refined, is largely used for edible and soap-making purposes.

Crude cotton-seed oil is of an intense ruby, nearly black colour, due to its holding in solution a powerful vegetable colouring principle. This peculiarity distinguishes it from all other oils. The oil-cells appear in the seed as brown specks dispersed through the albuminous matter.

Until the present refining process was discovered, the crude oil was practically useless for commercial purposes, as it communicated a powerful stain, due to the colouring matter it contained. This latter, according to results obtained by the author, amounts to 10 to 15lb. per ton of oil; the proportion, however, varies considerably. The woody husk of the seed also contains a large quantity of apparently the same nature.

This colouring matter has now been isolated by the author, with the result of throwing some light upon

* Of these, by-the-by, only 33.8 per cent. can be utilised for want of fuel, as pointed out by me in my patent of 1871, and verified four years later by the force of Nobel's blasting gelatin, in which the excess of 3.32 per cent. of oxygen is utilised by the dissolved gun-cotton, an explosive too rich in carbon.

its nature. In its dry state it is a light powder of pungent odour, of a brown earthy colour, and possessing powerful dyeing properties. A small proportion of it is soluble in water, but the principal bulk dissolves only in alcohol or alkalis, and it is upon the latter property that the success of the present refining process, and the method now proposed for treating the mucilage, is dependent. It is quite insoluble in all acids.

The following is a description of the method of expression and refining of the crude oil universally adopted in this country :—

The seed is first crushed by passing through rollers, and then ground to a fine state of division under edge-runners. When sufficiently reduced it is transferred to steam-jacketed kettles, and heated for about 10 minutes to a temperature sufficient to render the oil more easily expressible, and to coagulate the albumen of the seed. To this operation the author draws special attention, as it will be shown to have an important bearing upon the question of recovering the oil from the mucilage. From the kettles, the finely-ground and heated seed is placed in bags, each making a cake weighing about 10lb., and subjected to powerful hydraulic pressure for 15 minutes. The crude, nearly black oil, containing all the colouring matter in solution, is by this means expressed, and runs into a tank, from which it is transferred to the refinery. The next step is to remove the colouring matter, the process bringing the oil to a light straw or yellow colour.

This is effected in the method now in use, by treating the crude oil with about 10 to 15 per cent of caustic soda lye of 10° to 12° Tw. This operation varies considerably, but merely as to the quantity and strength of lye used, some refiners using a greater strength than that given, and less quantity. The quality of the oil governs this to a great extent, old oil requiring more lye than new, etc. A lye as strong as 40° Tw. is often used; within that limit the variation is almost purely a matter of choice, but the application is in all cases the same. The refining vessel used is an ordinary iron tank, but should be of fair depth. To a charge of 10 tons of crude oil, about 30 cwt. of caustic soda lye of 10° to 12° Tw. will be required. The lye, after preparation, is allowed to cool down to about 60° F., and the oil is refined cold. The tank is provided with a mechanical agitator, and the operation commences by a brisk agitation of the oil, which is maintained to the end. For this purpose air, instead of the agitator, driven by a pump through perforated pipes laid in the bottom of the tank, is often used; this action, though good, has a tendency, the author finds, to oxidise a portion of the oil, which becomes pure loss; and a considerable quantity of oxidised acid oil will often be found on analysis in the mucilage. The agitation by either of these methods being continued, the soda lye is allowed to run slowly and gradually into the oil through perforated pipes extending over the surface of the tank, so as to give an equal distribution. As the agitation proceeds the lye and oil mix, and the oil now gradually becomes full of black flocculent particles of soap, caused by the partial saponification of a portion of the oil by the caustic soda lye. The agitation is continued for about half-an-hour, and if, at the end of that time, a portion is taken out and allowed to stand, the soapy particles will be found to precipitate from the oil, which, if then nearly deprived of colour, the operation is finished; if not sufficiently free from colour, more lye must be added, and the agitation continued until the desired degree of whiteness is obtained. The charge of oil, after this operation is completed, is then allowed to stand for 12 to 15 hours, or until the

"mucilage," or partially-saponified portion of the oil with the liquid excess of lye used, has precipitated. If a strong lye has been used, this mucilage will be solid, but if weak lye is used, the soap will dissolve as formed in the excess of liquid, and the mucilage be sufficiently fluid to run. As soon as the mucilage has entirely precipitated, the clear refined oil is run off from the sediment, and the refining completed by the subsequent operations of washing and bleaching. The quantity of lye used is sufficient to saponify about 7½ per cent. of the oil, and a charge of 10 tons will be found to lose on the average about 15wt. by the operation. The loss, however, is not always the same, and varies with the quality and description of the oil used from 4 to 10 per cent.

The success of this process is evidently due to the property the colouring matter possesses of solubility in alkalis, the greater affinity of which removes the former from the oil. Unfortunately, however, the caustic soda used as a solvent produces an inevitable saponification of a portion of the oil, which is thus lost, and the alkali is also thus rapidly neutralised, and a larger quantity required than would otherwise be the case. The particles of soap, however, seem to be sufficiently alkaline at the moment of formation to enclose within them the colouring matter, which is thus precipitated from the rest of the oil. It is this principle of solubility in alkali, which the author, having ascertained, has carried further, and applied to the mucilage itself, thereby in turn refining it.

The crude oil contains a considerable quantity of free stearine, and this is more especially the case when the oil has been allowed to stand any time before refining; this free stearine is the first attacked by the lye in the refining process, and all goes into the mucilage, the grease in which is, therefore, of much better quality or "body" than the refined oil itself, but containing, in a condensed condition, all the colouring matter of the crude oil.

It would therefore appear, from the explanation of the process of refining the crude oil, just given, that "mucilage" is simply partially-made soap in the first stage of preparation, that might be readily made into finished soap by ordinary methods, but containing a large quantity of vegetable colouring matter unfitting it for industrial purposes. For some reason, however, not previously discovered, which has hitherto baffled all attempts to use it for the purpose, the mucilage has not been convertible into true soap, nor has it been found possible to sufficiently free it from the colouring matter. The mucilage has, therefore, always been sold at a nominal figure to grease distillers for manufacture into stearine—chiefly employed in inferior candles, and the adulteration of tallow. The portion of oil saponified in the refining process is, therefore, practically at present almost pure loss to the refiner. It is this loss which, in the form of mucilage, the author has made the subject of investigation. As a result, he gives the methods to be described for regenerating and recovering the oil hitherto lost, "as refined and decolourised fatty acids," the colouring matter being extracted for use as a dye. The fatty acids, as recovered, can be dissolved in the refined oil, or used direct for soap-making purposes. This amounts to practically refining cotton-seed oil without loss in weight.

The first methods employed by the author with mucilage were chiefly for the purpose of extracting the colouring matter it contained for use as a dye. The mucilage was dissolved in four or five times its weight of water, made strongly alkaline by the addition of caustic soda lye to effect the solution of the colouring matter. The resulting soap was then separated by the addition of common salt, and the excess lye, being strongly alkaline, retained a considerable por-

tion of the colouring matter in solution. By neutralising the excess lye with sulphuric acid, the colouring matter was precipitated, and then separated and dried. The soap obtained by this means was useless, always remained of a purple colour, which gave a strong stain, and on boiling upon a saline solution, for the purpose of conversion into bar soap by the usual method, was converted into thick frothy scum, the curds of which did not coalesce upon becoming quiescent, and always remained mixed with more or less of the black lees. Care was taken that the solution of soap was not made so dilute as to cause the soap, on separation, to be precipitated as a di-stearate of the alkali, which would be afterwards inconvertible into true soap, and there was no apparent reason why the oil of the mucilage should thus work differently from other cotton oil, and refuse to make soap. This was, however, the result that has always attended more or less the efforts to utilise mucilage for soap. The author found that the use of salt as a separant was largely the cause of the effects experienced, that it tended to reduce the solubility of the colouring matter, thus preventing its removal, altered it from its natural colour of yellow to a disagreeable blackish purple, and for a reason afterwards discovered and to be described, produced the frothy character of the soap.

A greatly improved result was obtained, therefore, by entirely substituting caustic soda lye for common salt as a separant. By this means a perfectly clear soap of smooth close texture and good weight was obtained, and the great solvent power of the caustic soda lye sufficiently decolourised it for dyers' use. The soap obtained by this method, when freshly cut, was of a light yellow colour, and perfectly transparent, the exposed surface rapidly oxidising to a brown. The blackish purple colour, always the result of the use of salt, was avoided, and the soap gave no stain. It usually contains about 50 per cent. fatty acids; if required more concentrated, it must be boiled upon salt after decolourisation.

It was by this means possible to convert mucilage to good soap, and the author next turned his attention to producing from it refined fatty acids, which should be completely decolourised, and equal to ordinary refined oil. This further improvement was effected in one method by dissolving the brown soap obtained as described, and mixing with it 20 to 25 per cent. of an inert powder, such as finely-ground chalk, etc. On the addition of strong caustic lye, the soap precipitated very curiously with the chalk in a very minute division, and the remaining colouring matter of the soap dissolved in the excess lye. The completely decolourised fatty acids were liberated from the mixture by sulphuric acid. Another method consisted of boiling the solution of brown soap, made strongly alkaline, with 10 to 15 per cent. powdered peroxide of manganese or hydrated peroxide; on adding dilute sulphuric or hydrochloric acid the fatty acids as liberated were bleached.

Both these methods were superseded by the plan of bleaching the brown soap with calcium hypochlorite or bleaching powder, this improvement satisfactorily completing the methods of conversion of mucilage into refined acid oil. The detail of these methods is as follows:—

The raw mucilage, say in charges of 5 to 10 tons, is heated by open or close steam in a lead-lined tank to a temperature not exceeding 110° to 120° F.; dilute sulphuric acid is then added in small quantities gradually to avoid frothing, the charge after each addition being well agitated, and this is continued until the mucilage is completely decomposed. The charge must be kept neutral, and no excess of acid used. With excess of acid and great heat, the colour-

ing matter is affected and injured, and the alteration it undergoes renders its removal from the soap less easy. When the decomposition is complete—but the charge being quite neutral—the temperature is raised until the separated fatty acids are thoroughly melted, a few minutes being usually sufficient. The whole is then allowed to stand until the perfectly black fatty acids have collected on the surface. The useless saline liquor is run off. The acid oil so obtained, when cold, is of fairly solid consistence, and by analysis usually tests:—

80 per cent.	actual fatty acids.
1t	water.
9	colouring matter.
100	

Its retention of so much water is probably due to the strong hygroscopic nature of the colouring matter.

This acid oil is saponified with caustic soda lye in an ordinary soap copper, close steam being used. To every hundredweight of actual fatty acids present is added, when melted, the proportion of 152lb. of caustic soda lye of 17° Tw., and the whole boiled for a few minutes until the oil is saponified; this takes place very rapidly, the oil being fatty acids. The soap so formed, which will be nearly neutral, requires to be separated from the excess of liquid used. To effect this the boiling is continued, and 28lb. of lye of 70° Tw. in the same proportion gradually added in portions until the soap opens to a fairly strong curd, and is completely separated. The heat is now withdrawn, and the charge allowed to remain quiescent for one to two days; in that time the excess lyes completely precipitate, the curds of the soap coalesce, and a clear brown soap of good weight and close texture is the result. The excess lyes are drawn off, and the soap is then ready for bleaching.

In this process is clearly shown the effect of the solubility of the colouring matter in alkaline lyes. The solution of soap when boiling is of an intense black colour, but immediately on the addition of the strong lye of 70° Tw., the soap separates in curds of a bright reddish yellow colour, while the lyes remain intensely black. The separated soap being almost neutral, the strong alkaline lyes, by reason of their affinity for the colouring matter, have retained it in solution. So much is this the case that on cooling, the excess lyes often congeal to a consistence, through the presence of colouring matter, that allows of their being cut with a knife.

The operation that has been described of the extraction of the colouring matter by caustic soda, can be supplemented, if desired, by the ordinary operation of "fitting." To the brown soap remaining, after the black lees have been drawn off, sufficient water is added to dissolve and run the curds together, but no more, and the close soap then boiled for two or three hours, until the head or "fob" of froth has worked out; it is then left, if the charge is considerable—say 3 or 4 tons—for two days. In that time the excess of alkali, carrying with it a considerable quantity of colouring matter, and some portion of thin soap, subsides. This forms the "nigre," upon which floats a perfectly clear soap. From this the fob is skimmed off, and the nigre separated. This operation of fitting is not in any way essential, but by the further removal of colouring matter it economises the calcium hypochlorite in the succeeding bleaching process. Before proceeding to this latter, it may be well to consider the operations that have been described.

The preliminary decomposition of the mucilage by sulphuric acid into acid oil, is for the purpose of after economy in caustic soda, and is only necessary when

the raw mucilage contains so large a proportion of liquid, that to separate the soap from it by means of caustic soda would require a prohibitive amount of the latter. If the mucilage should contain as much as 30 to 40 per cent. of acid oil, the decomposition can be omitted with economy. For instance, to ensure the complete separation of the soap from its solution, it is usually necessary to bring the excess lyes to a strength of 18° to 20° Tw. The average quality of mucilage usually contains about 75 per cent. liquid, etc., and 25 per cent. acid oil. This makes only a thin solution of soap, and to separate the latter will require the addition, if treated direct, of 180 lb. of caustic soda lye of 70° Tw. per cwt. of fatty acids present. This quantity is allowing for the acid oil taking up its own weight of water to form soap, and the remaining excess lyes being of a strength of 20° Tw. The amount of caustic soda lye used, when the mucilage is previously decomposed, is only equivalent to 74 lb. of 70° Tw. per cwt. of oil, a saving of considerably more than one half, notwithstanding that this method necessitates the resaponification of the oil. The economy of this last process is due to the fact of acid oil being saponifiable in lye of any strength, whereas neutral oil is not saponifiable in lye exceeding a strength of 10° to 12° Tw., necessitating a large excess of liquid from which the soap has to be afterwards separated. The decomposition of the mucilage yielding the acid oil in a concentrated form, it can be resaponified in lye of great strength—70° Tw.—consequently the excess lyes can be regulated to any desired quantity, no more being used than is absolutely necessary for the soap to boil on without burning. The quantity of lye will always be sufficient for the solution of the colouring matter. The strength and quantity of the lye of 17° Tw. used is so regulated as to provide the alkali necessary to saponify the oil, sufficient water to form the soap, and also excess lyes of 20° Tw., which latter, with the after addition of the strong lye of 70° Tw., will amount to $\frac{2}{3}$ of the fatty acids, or $\frac{2}{3}$ of the soap in weight; this is allowing for the 11 per cent. of water contained in the acid oil. The proportion of excess lyes stated will usually be found sufficient with a suitable soap pan, and economy in this respect is of vital importance. Open steam should not be used, as the large amount of condensation reduces the strength of the lye, and necessitates a larger quantity.

All mucilage varies very much as to its proportions—from 60 to 85 per cent. of water,—and in the case of mucilage treated direct without decomposition, the quantity of lye named must be altered according to the percentage of water present. The additions of lye must be continued until the soap is judged to be well and sufficiently separated.

Although the caustic soda process that has been described removes the bulk of the colouring matter and deprives the soap of its staining power, the latter still remains of a brown colour that even repeated applications of the caustic soda lye will not remove, supposing such to be economically practicable. The complete decolourisation of the soap and acid oil is effected by bleaching with calcium hypochlorite.

The brown soap is melted in a lead-lined tank, with a small quantity of water, and boiled by means of open or close steam. While boiling, bleaching powder, made into a cream with water, is added gradually in portions, and the soap begins to bleach, assuming first a bright red colour. The reaction is very energetic, mutual decomposition ensuing, the chlorine uniting with the soda of the soap to form sodium chloride. The fatty acids thus liberated are completely bleached, precipitating as a white insoluble lime soap. Ten to fifteen per cent. of the

calcium hypochlorite will be requisite for complete decomposition of the soda soap; but the latter will often be sufficiently bleached when only partial decomposition has occurred. In such cases the amount of bleaching powder will be less; the additions must be gradually continued until the desired colour is attained. Strong solutions of the soap bleach more effectually than weak. The sodium chloride solution is run off, and the bleached lime soap, or mixed lime and soda soap, as the case may be, in turn decomposed into fatty acids and sulphate of lime, by boiling with dilute sulphuric acid. When the reaction is completed, the calcium sulphate and liquid are allowed to settle, and the hot melted fatty acids run or ladled into another vessel, where they are well washed with water to remove all excess of mineral acid.

The first attempts at bleaching with hypochlorites were made with the sodium salt, thus avoiding the decomposition of the soap. Sodium hypochlorite, however, on heating, is at once reduced to chlorate, consequently only a portion of the chlorine is available for bleaching. Moreover, the chlorate formed, immediately separates the soap, and on soap not in solution the bleaching action is very slight, only the surface being acted upon. With sodium hypochlorite, therefore, repeated applications of the salt would be requisite to fully bleach the soap; and as compared with the calcium salt, in which the whole of the chlorine is obtained in the most effective manner possible, and the bleaching rapid and complete, the expense and trouble of the former treatment would be prohibitive, and attempts in that direction may therefore be dismissed.

A reference has been made to the fact that mucilage had always been found to be inconvertible into true soap, the reason of which was unknown.

It has been seen that the substitution of soda lye for salt as a separant, removed the difficulty experienced so far as regarded decolourisation, and the light frothy character of the soap, and with much of the mucilage commercially available the process that has been described accomplished its conversion into refined acid oil. In the case of the major quantity of mucilage obtainable, the caustic soda treatment only presented the old difficulty of conversion into soap in a fresh form. This consisted of the impossibility of completely separating the soap from its solution. In all cases where this has occurred, the author has ascertained that the effect was due to the presence of albuminous matter in the mucilage, and that apart from the question of decolourisation, this was the reason of mucilage having been inconvertible into soap. In a sodium chloride solution the albuminous matter is insoluble, and the soap on separation therefore takes it up, acquiring the frothy character described. In an alkaline solution, the albumen is soluble, and remains in the excess lyes; the soap separated by means of strong caustic lye is therefore free from it; but a considerable portion of the soap remains in solution with the albumen, and cannot be extracted. The author has recently succeeded in meeting this difficulty by neutralising the albumen by means of lime. The due proportions of caustic soda lye are first added to the charge of mucilage, or of black acid oil, in the manner that has been detailed. If no albumen is present, all the soap will thereupon separate, and nothing further is necessary. But in exact proportion to the quantity of albumen that may be in the charge, a certain amount of soap will be retained in solution by it, a portion only separating on the addition of the lye; if the albumen be in sufficient amount all the soap will remain in solution. In such case, while the charge is boiling, milk of lime is added gradually in portions; the

albuminate of soda formed by the previous addition of the caustic soda lye is thereby decomposed, and an insoluble albuminate of lime precipitates. This being inert, the soap previously held in solution thereupon separates. The lime albuminate precipitates with the excess lyes, and the soap is ready for bleaching. The addition of lime must be continued until it is found that all the soap has separated from solution. The latter can be ascertained very simply by taking from the charge a small sample of the excess lye, and rapidly cooling it, or adding a little lime. If in either case soap separates, more lime must be added to the charge; this is always supposing that the non-separation is not due to insufficient soda lye. Care must be taken to use no excess of lime, which would decompose the soda soap.

The saponification and decolourisation by caustic soda lye; removal of albumen, if present, by lime; bleaching by calcium hypochlorite; and decomposition by mineral acid, completes the operations necessary for the conversion of mucilage to refined acid oil.

In dealing with mucilage, the effect that has been experienced of albumen on solutions of soap, is very curious. Ordinarily, soap is not soluble in soda solutions exceeding 1.060 to 1.070 specific gravity; but in instances where the excess lyes would have tested 1.350 specific gravity, the bulk of the soap still remained in solution. Exactly the same result is obtained by incorporating egg albumen or cotton-seed with tallow or other soap. Albumen therefore possesses the property of rendering soap soluble in alkaline solutions of any strength. If the albumen is present in a small proportion only, the bulk of the soap will separate on the addition of the lye, and the remainder on becoming quite cold; if the proportion of albumen be increased, less soap will separate, and so on until the whole of the soap remains soluble even upon cooling. Refined cotton-seed oil, saponified and dissolved with 25 to 30 per cent. of its weight of cotton-seed, is inseparable with any strength or proportion of lye. In the case of mucilage, the soap separated by cooling the excess lyes was not decolourised, nor could it afterwards be so. The quantity of soap separated can be increased by removing it as fast as it forms on boiling; the exposure of a fresh surface to the atmosphere apparently having the effect of causing a further separation. If, however, the soap so formed is allowed to remain quiescent on the lyes, it redissolves.

The albuminous matter in the mucilage is found to consist of the finer portions of the cotton-seed which are abstracted by the crude oil. In the process of refining, the albumen is dissolved by the caustic soda lye, and thus passes into the mucilage. The reactions which mark its presence are very distinguishable on decomposing the latter. Should the mucilage contain albuminous matter or cotton-seed, on treating it with sulphuric acid, the separated liquid will be of a bright yellow colour, which, on standing, gives a granular deposit of vegetable albumen. The larger quantity of the latter present in the mucilage will be taken up by the liberated acid oil; this, if the proportion of albumen be considerable, consequently acquires a tough plastic consistence, and is difficult to saponify. The mixture is often of greater specific gravity than water. If heated beyond a temperature of 120–130° F. it assumes an intense green colour, and soap made from it is the same. Below a temperature of 100–110° F. the colour is not affected. It is on this account of the greatest importance that in the case of albuminous mucilage, the temperature of the acid oil should not at any time previous to

saponification and the lime treatment be raised to a temperature exceeding that named, otherwise, owing to the colour assumed, it would become useless.

The reaction furnishes an infallible guide. If a sample of the black acid oil on heating beyond 130° F. turns green, lime will be required; if the colour remains unaltered, the caustic soda process alone is requisite. By dissolving the green acid oil in alcohol, a bright green solution is obtained; on filtration the albumen remains as a green insoluble residue. This method allows of the estimation of the albumen.

With the exception of its preventing the separation of the soap, the seed gives no special characteristics to the mucilage itself, and is not visible in it. This is probably the reason it has so long escaped detection.

Under the great hydraulic pressure to which the seed is subjected, much of the finer portion passes through the bags with the crude oil. If the latter is allowed to stand for a short time, the seed precipitates as a slinky deposit, and can be removed. It was attempted to adopt this method for the purpose of preventing the albumen passing into the mucilage, but without success. After carefully separating from a charge of oil, before it was refined, all the insoluble matter it contained, the mucilage was still found to hold so large a proportion of albuminous matter as to render it unworkable. The crude oil must therefore have had a considerable quantity of seed in solution, and this is a fact not hitherto suspected, and to which serious losses in weight of seed during crushing are probably due. A considerable percentage may thus escape undetected. This will be readily recognised, as mucilage containing 15–20%, and even 35 or 40% of hulled seed is often met with. One lot of 1000 tons of seed was found to have lost 5% in crushing, and the mucilage contained a large proportion of albuminous matter. In the mucilage it is of course worth nothing, only interfering with the recovery of the fatty acids, which are alone of value. On this account, and the serious losses due to the waste of seed, the matter is one for the attention of manufacturers, with a view to overcoming the difficulty, and preventing the escape of seed. The author offers the suggestion that the cause probably lies in the operation to which he drew attention—of heating the seed in the kettles. It is possible that the oil derives its power of dissolving the [seed from the latter having been imperfectly heated, and for too short a time and at too low a temperature to thoroughly coagulate the albumen.

If the colouring matter be not separated from the excess lyes, or it is more desirable to recover the soda, they can be evaporated to dryness and the soda calcined. The vegetable matter is thus destroyed, and by lixiviation the soda is ready after causticising for re-use. The strength of the lyes allows of this being economically done, and the cost of the process thus materially reduced. It requires an expenditure of less than four tons of fuel per ton of soda ash of 45° recovered.

The characteristics of the colouring matter have been described. Its preparation is effected by first filtering the excess lyes to remove from them all particles of soap that may not have been previously separated. To the clear solution thus obtained, dilute sulphuric acid is added gradually until the alkali is completely neutralised. The colouring matter then separates as a flocculent precipitate. This is collected on a filter, carefully washed to remove all excess of acid, and dried slowly at a low temperature. It is then ready for use as a dye, and gives perfectly fast colours on both wool and silk, resisting the action of light, acids, and alkalis.

To dye a direct colour—for a bath of ten pounds of woollen yarn—seven ounces of the dye, dissolved with seven ounces of carbonate of soda ($\text{Na}_2\text{CO}_3 \cdot 10\text{H}_2\text{O}$) is used, boiling for three hours.

To produce in the ordinary manner a corresponding shade, requires—

5oz. Bichrome.
3oz. Cudbear.
3oz. Extract of Fustic.
 $\frac{1}{2}$ oz. Logwood.

Another method is to prepare the bath by dissolving the colouring matter with the requisite amount of alkali, and then precipitate it by neutralisation with sulphuric, hydrochloric, or acetic acid; if care be taken to use no excess of acid, the colouring matter remains in suspension in a very fine state of division. If an excess of acid be used it clots in particles too large to enter the fibres of the wool, and is useless. In a state of suspension, the colouring matter is taken up by the wool immediately, and the operation is much shorter than when used in solution. On the other hand, however, the wool is liable to be only surface dyed, and in the operation of scouring the shade will be much lightened.

In using solutions, no more alkali should be used than is absolutely necessary to dissolve the dye, as the attraction of the alkali neutralises the attraction of the wool for the colouring matter.

A richer shade is obtained by using wool previously mordanted in the usual manner by working in a bath of bichromate of potash; this deepens the shade, giving a warm brownish red.

The shades and colours can be varied to any extent by combinations with the other colouring matters.

With the whole range of aniline colours, the cotton-seed colouring matter seems to possess the property of forming definite chemical compounds, the nature of which is not yet fully investigated. These are formed by dissolving equal weights of the cotton-seed colouring matter and $\text{Na}_2\text{CO}_3 \cdot 10\text{H}_2\text{O}$ in water. This is then strained, and to the solution so obtained is added a previously prepared solution of an aniline dye; the strength and quantity of the latter is governed by the nature of the shade required, which is a matter of choice. The whole is agitated until thoroughly mixed, and a weak solution of H_2SO_4 slowly poured in until the Na_2CO_3 is neutralised. The colouring matter precipitates, and is separated, washed and dried. The compound thus obtained is not decomposable by boiling water, it possesses the brilliancy of the aniline, but the characteristics of the vegetable colouring matter, being soluble only in alkalis and alcohol, and perfectly fast. The cotton-seed colouring matter acquires the colour of the aniline used, and only a small proportion of the latter is necessary. In this way an infinite variety of brilliant dyes of perfect fastness may be obtained.

The methods of dyeing silk are analogous to those already described for wool.

If the colouring matter is heated to boiling point with its own weight of $\text{Na}_2\text{CO}_3 \cdot 10\text{H}_2\text{O}$, and six times its weight of water, the whole being stirred until dissolved, it will on cooling set to a solid paste. In this form it is very readily soluble, and more convenient for dyeing purposes than the dry powder.

A slight drawback of the colouring matter has been found to be in a tendency to impart a faint feeling of harshness to the wool, unless the dyeing be carefully conducted. This may be a natural property of the dye, but is more likely, when it occurs, the result of the alkaline treatment it goes through in the process of preparation, and will probably yield to further investigation.

DISCUSSION.

Mr. GOSSAGE thought that English cotton-seed mucilage could hardly contain as much as twenty-five per cent. of oil. Judging from the difference between the prices of crude and refined cotton oil, the loss in refining could not be more than five per cent., and indeed was generally much less. The author had not given sufficient information to enable them to judge whether the colouring matter derived from the mucilage could be obtained at such a price as to make it a marketable commodity. That the mucilage sometimes contained a very large proportion of albumen, and that it could be separated by means of lime, were among the most interesting features of the paper.

The CHAIRMAN said he understood the author to say that the colouring matter referred to was very like tar, and also a good dye when isolated, and mixed with aniline dyes. If the meeting could hear something about the properties of this colouring matter, it would be useful. Was it not possible to get rid of the albumen by coagulating it before pressing the seed?

Mr. NORMAN TATE had listened attentively to the paper, but, although it gave many details of processes, he could not find in it anything particularly new. He was surprised to hear that in the mucilage so large an amount as twenty-five per cent. of oil remained, as this was very considerably above what was found in ordinary English mucilage. There were mucilages in commerce which contained as much as fifty per cent. of fatty matters, but these were exceptional, arising from some particular mode of expressing and treating the oil. The paper was useful as giving details of results obtained in certain experiments. Such records of failures and successes had their uses, but in his opinion there was nothing in the process which could supersede those now most generally in use. The Chairman had suggested the elimination of albuminous matters by coagulation. Heating the seed or oil might do it, but unless it were done with great care, the results might be neither economical nor salutary. He would like to have heard more about the colouring matter, as disadvantages arising from its use and discussions respecting it were constantly arising.

Mr. W. P. THOMPSON stated that he had seen small samples of cloth dyed by this material ranging in colour from a light straw colour to a rich dark brown. The dyestuff itself had an appearance between snuff and ground coffee, and had a strong pungent smell. He had on one occasion asked the author the very question suggested by the Chairman, as to whether they could not coagulate the albumen after expression of the oil; but, if he remembered rightly, the author had stated that heating the oil itself sufficiently to coagulate the albumen would injure both the oil and the dyestuff, while no result would be obtained by heating the mucilage, as the albuminate of soda would not coagulate.

Professor CAMPBELL BROWN said that he regretted the author's absence, because he might have been able to give them some of the experimental foundations for his rather large statement, that the colouring matter of the oil formed chemical compounds with nearly all aniline dyes. If one knew the nature of these compounds (if they existed) one would probably know the chemical nature of the colouring matter of the oil itself. The paper as a whole showed that a great amount of time and work had been spent on the investigation, much of it labour that might have been saved if the experiments had been carried on in a systematic and philosophical manner. For instance, if the composition of the specimens

used and of the products obtained had been ascertained at each stage, the author would have very soon arrived at the principal result—namely, the presence of the substance, whatever it was, which had been called albumen in the paper, and the necessity for its absence in order to obtain success. In this way all the intermediate stages of failure would have been avoided. The age of random experiment was now past, and practice must be guided by theoretical knowledge in order to attain success.

The CHAIRMAN regretted that the author was not present to answer the various questions which had been raised. What they wanted to know was whether the real colouring matter could be isolated, and whether it was capable of industrial application, the instances of silk dyeing cited seeming to have been only experimental.

Meeting held April 7, 1886.

COWLES' ALUMINIUM FURNACE.

BY W. P. THOMSON.

THE new departure in metallurgical science forming the subject-matter of this paper is the invention almost exclusively of Messrs. Eugene H. and Alfred H. Cowles, of Cleveland, Ohio, and is covered in this country by a series of five patents taken out by me as communications from them. This paper is mainly a compilation from data letters, reports, and extracts, kindly furnished by Messrs. Cowles and their European commercial agent, Mr. Ben. M. Plumb, for the most part unpublished as yet in this kingdom. That the invention is rightly termed a new departure must be acknowledged by every one, when they learn that chromium, titanium, silicon, aluminium, calcium, and the other alkaline earth metals are obtained by direct reduction of their oxides by means of carbon, till a year ago almost universally considered a practical impossibility. By this process aluminium can be produced upon a large commercial scale in its various alloys at a cost of two shillings per pound. The process has for some months been at work on a small manufacturing scale, and before describing it by aid of the accompanying diagrams, I will read the brief description by Mr. Eugene Cowles (given at the annual meeting of the Franklin Institute of Philadelphia, in January last) of the actual plant used for driving the electric furnace, the main feature of the invention.

The Dynamos.—These are, of course, placed in the dynamo-room, as near as possible to the driving-shaft, where they can be kept free from any dust or grit from the furnace-room. The larger of these is by far the most powerful machine ever built by the Brush Electric Company. It weighs over seven thousand pounds, and at a speed of 907 revolutions per minute produces a current of 1575 amperes, with an intensity of 46.7 volts. It is of the shunt-wound type of dynamo, built for the purpose of incandescent lighting; further than being of greater capacity, and having a hub made of the Cowles aluminium brass, which exhibited a tensile strength of 95,000 pounds per square inch and 5 per cent. elongation, this dynamo does not differ from the ordinary machine.

Conduction of the current of the large dynamo to the furnace in the furnace-room and back to the machine, is accomplished by a complete metallic circuit, except where it is broken by the interposition of carbon electrodes, and the mass of pulverised carbon in which the decomposition of the ore takes place. This circuit consists of thirteen copper wires,

each 0.3 inch in diameter. There is likewise inserted into this circuit an ampère meter through whose helix the entire current flows, indicating, by its suction of a plunger armature attached to a spring balance and dial-faced indicator, the total strength of current being used.

This ampere meter is an important element in the management of the furnace, as by the position of the finger on the dial the furnace attendant can tell to a nicety what is being done by the current within the furnace. It is placed upon a shelf in a good light, near to and in full view of a person in any position about the furnaces.

Between the ammeter and the furnace in the furnace-room, and forming part of the circuit, is placed a large resistance coil of German silver immersed in water, a heavy copper slide passing backwards or forwards as desired, throwing more or less of this resistance into the circuit, and almost the entire energy of the current may be thus applied to heating water. The object of the resistance box is to serve as a safety appliance. It is used by the furnace operator when it is desired to change the current from one furnace to another, or if it be necessary to choke off the current almost entirely before breaking it by a switch, thus preventing serious flashing at the commutator of the dynamo or at the switch. It is likewise of value should any evidence of a short circuit appear in the furnace or elsewhere.

The furnace is simple in construction, being what might be called a rectangular box A, one foot wide, five feet long inside measurement, and fifteen inches deep, and made of fire-brick. From the opposite ends, through pipes B the two electrodes CC and holders pass. The electrodes are immense electric-light carbons, three inches in diameter, and thirty inches long. If larger electrodes be required, a series this size must be used instead, as so far all attempts that have been made to make carbons of larger size that will not disintegrate on becoming incandescent have failed. The ends of the carbons are placed within a few inches of each other, in the centre of the furnace. In the circuit between the furnace and dynamo is placed the resistance box and the ammeter. The resistance box is so constructed that a variable resistance may be thrown into the circuit, if such be desired in controlling the current. The ammeter was designed by Mr. Brush, and is so constructed as to take from fifty to two thousand amperes of current around its helices and register the same upon its dial.

These connections having been made, the furnace is now ready to receive the charge. The walls of the furnace must first be protected, otherwise the intense heat generated within the interior would cause the fire-brick to melt and flow like water. What is the best substance to line the walls with? Finely-powdered charcoal is comparatively a poor conductor of electricity. It is considered infusible, and is the best non-conductor of heat of all known solids. From these properties it would seem to be the best material to use as a lining for the furnace. So long as the air is excluded it is impossible for it to burn. But it is found after using pure charcoal for a few times that it becomes valueless. It retains its woody structure, as is shown in the larger pieces, but it has changed to graphite, becoming a good conductor of electricity, and thereby it tends to diffuse our current through the lining, heating it and the walls. The fine charcoal is therefore washed in a solution of lime water. After drying, each particle is insulated by a fine coating of lime. The bottom of the furnace is now lined to a depth of two or three inches with this prepared charcoal D. A sheet-iron gauge is placed

along the sides of the electrodes, leaving about two inches between it and the side walls. In this space more fine charcoal is placed. The charge E, consisting of about twenty-five pounds of the oxide of aluminium, twelve pounds of charcoal and carbon, and fifty pounds of granulated copper, is now placed within the gauge, and spread around the electrode to within a foot of each end of the furnace. In place of granulated copper, a series of short copper wires or bars can be placed parallel to each other and transverse to the furnace among the alumina and carbon.

in the plan annexed, and from this cause the internal resistance of the furnace may be too low for the dynamo and cause a short circuit. The operator therefore throws sufficient resistance within the circuit, by means of the resistance box (not shown) to make it safe to start the dynamo. This being done, he gradually takes the resistance of the box out of the circuit, and by watching the ammeter, and now and then moving one of the electrodes out a trifle, he is enabled to prevent undue short-circuiting in the beginning of the operation. In about ten minutes the copper between the electrodes has become melted,

SECTIONAL PLAN.

LONGITUDINAL SECTION.

TRANSVERSE SECTION.

After this is done a bed of charcoal F, the granules of which vary in size from that of a chestnut to that of a hickory nut, is spread over the charge and the gauge withdrawn. This coarse bed of charcoal above the charge allows free escape for the carbonic oxide gas generated during the reduction. The charge being in place, an iron top G lined with fire-brick is placed over the whole furnace, and the crevice luted to prevent the entrance of air. The brick of the walls insulate this cover from the current.

Now that the furnace is charged and the cover luted down, it is started. The ends of the electrodes were in the beginning placed close together, as shown

and the latter are moved far enough apart so that the current becomes steady. The current is now allowed to increase till about thirteen hundred amperes are being drawn from the dynamo, driven by fifty volts. Carbonic oxide gas has already commenced escaping through the two orifices in the top, where it burns with a white flame. By slight movements outward of the electrodes during the coming five hours, the internal resistance of the furnace is kept constant, and at the same time all the different parts of the charge are brought in turn into the zone of reduction. At the close of the run the electrodes are in the position shown in the accompanying elevation, the

furnace is shut down by placing a resistance in the box, and then the current is switched into another furnace, which has been charged in a like manner.

This regulating of the furnace by hand is rather costly and unsatisfactory. Several experiments have therefore been tried for making it self-regulating, and on the 26th of January last, a British patent was applied for by Messrs. Cowles, covering an arrangement for operating the electrodes by means of a shunt circuit, electro magnet and vibrating armature. If the electrodes were drawn back and exposed to the air in their highly-heated state, they would be rapidly wasted away. To obviate this, Messrs. Cowles place what might be called a stuffing box round them, consisting of a copper box filled with copper shot. Copper, on account of its well-known properties of conducting heat and electricity, is preferable in most cases to other substances for this purpose. The wires are attached to the boxes instead of direct to the electrodes. The hot electrodes, as they emerge from the furnace, first encounter the shot, which rapidly carries off the heat, and by the time they emerge from the box they are too cool to be oxidised by contact with air.

During one operation of five hours required for the above-mentioned charge, there has been, one might say, pumped into the furnace ninety electrical horse-power, which, if it were devoted to heating the fifty pounds of copper alone contained within the furnace, would raise it to a temperature of two hundred and forty-two thousand degrees Fahrenheit, were such a thing possible. During the beginning of the operation, the copper first melted in the centre of the furnace. There was no escape for the heat that was continually generated. The temperature increased till the refractory corundum melted, and, being surrounded on all sides by carbon, gave up its oxygen. The heat of the union of the oxygen liberated from the aluminium uniting with the carbon, has certainly aided in the economy of the process. The copper has had nothing to do with the reaction, as it will take place in its absence.

Whether the reduction is due to the intense heat, to electrolytic action, or both, is difficult to say. If it be electrolysis, it is Mr. Cowles' impression that we have here a case where electrolysis can be accomplished with an alternating current, although it has not been tried as yet. Were the copper absent, the freed aluminium would now absorb carbon and become a yellow crystalline carburet of aluminium; but, instead of that, the copper has become a boiling, seething mass, and the bubbling of its vapours may be distinctly heard. The vapours probably rise an inch or two, condense, and fall back, carrying with them the freed aluminium. This continues until the current is taken off from the furnace, when we have the copper charged with from fifteen to thirty per cent., and in some cases as high as forty per cent. of its weight of aluminium, and a little silicon. After cooling the furnace, this rich alloy of aluminium and copper is removed.

Another valuable property of the fine charcoal is that the metal does not spread and run through its interstices, but remains a liquid mass surrounded below and on the sides by fine charcoal, the fine charcoal sustaining it just as fine flour or other dust will sustain drops of water for considerable periods without allowing them to sink in. The alloy presents a white appearance and the brittle nature of the sample I have in my hand. This metal is now melted in an ordinary crucible furnace, poured into large ingots, and the amount of aluminium it contains is determined by analysis, after which it is again melted, and the requisite copper added to make the valuable aluminium bronzes, of which I will speak later.

Two runs, as described, will produce in ten hours' average work, about one hundred pounds of this white metal, containing about fifteen pounds of aluminium. From this data it has been carefully estimated that aluminium itself, in its alloys, can be produced at about forty cents. a pound in the works now being erected by the Cowles Electric Smelting and Aluminium Company, at Lockport, New York. This estimate is based upon the present size and form of furnace.

The Cowles Electric Smelting and Aluminium Company will shortly have facilities for concentrating within one furnace the energy of twelve hundred horse-power. With a larger furnace, there is no reason why it should not be made to run continuously like the ordinary blast furnace.

The temperature attainable within the furnace is only limited by the fusion point of carbon; as yet we have not reached this limit. The charcoal is easily changed to graphite, but so far it has always retained its woody structure.

Pure white sand is not only made to melt, but is easily reduced to silicon. A mass of minute crystals of silicon was obtained from a fire-brick being placed within the furnace and too near the centre of heat. The other elements that were present seem to have volatilised, leaving nothing but the silicon behind.

Boron, sodium, potassium, calcium, magnesium, chromium, and titanium have all been reduced from their oxides by means of carbon in the furnace. It is safe to say that no metallic oxide can resist the intense reducing forces that are here brought to bear upon it.

In the operation of the furnace, copper was used to gather the aluminium together, and prevent its formation into carburet of aluminium, or into amorphous powder. The copper acts somewhat as a condenser to the metallic fumes of aluminium liberated. In place of the copper, any non-volatile metal may be used as a condenser, to unite with any metal it may be desired to reduce; provided, of course, the two metals are of such a nature that they will alloy with each other at this high temperature. In this way, aluminium may be produced and obtained, alloyed with iron, nickel silver, tin, or cobalt. Messrs. Cowles have made alloys containing 50 per cent. of aluminium and 50 per cent. of iron; 25 per cent. of aluminium and 75 per cent. of nickel; 30 per cent. of aluminium and 70 per cent. of copper. I have here some of these alloys. Silicon or boron, or other rare metals, may be combined in the same manner, or tertiary alloys may be produced—as, for instance, when fire clay is reduced in the presence of copper we obtain an alloy of silicon, aluminium and copper. This is a white, brittle alloy when more than ten per cent. of aluminium and silicon is present in the copper. With from two to six per cent. of aluminium and silicon in equal proportions, the alloy is stronger than gun-metal, has great toughness, does not oxidise when heated in the air, and has fine variations of yellow gold colour.

The alloys which the metals obtained by the methods above described form with copper, have been made the subject of careful study. An alloy, containing 10 per cent. of aluminium and 90 per cent. of copper, forms the so-called aluminium bronze, with a fine golden colour, which it retains for all time. The 5 per cent. aluminium alloy is a close approximation in colour to 18 gold, and does not tarnish readily. Its tensile strength in the form of casting is equivalent to a strain of 68,000 pounds to the square inch. An alloy, containing 2 or 3 per cent. aluminium, is stronger than brass, possesses greater permanency of colour, and would make an excellent substitute for that metal. When the percentage of aluminium reaches 13, an exceedingly hard, brittle alloy of a

reddish colour is obtained, and higher percentages increase the brittleness, and the colour becomes greyish black. Above 25 per cent. the strength again increases.

The effect of silicon in small proportions upon copper and aluminium bronze is to greatly increase its tensile strength. When more than 5 per cent. is present the product is exceedingly brittle, and greyish black in colour. It is probable that silicon acts to a certain extent as a fluxing material upon the oxides present in the copper, thereby making the metal more homogeneous. On account of its superior strength and high conductivity for electrical currents, silicon bronze is the best material known for telegraph and telephone wire, and is now in large use on the Continent for this purpose, its conductivity being almost the same as and its tensile strength being double that of copper.

The element boron seems to have almost as marked an effect upon copper as carbon does upon iron. A small percentage in copper increases its strength to 50,000 or 60,000 pounds per square inch without diminishing to any extent its conductivity.

Aluminium seems to increase very considerably the strength of all metals with which it is alloyed. An alloy of copper, nickel, and zinc, containing a small percentage of aluminium, called Hercules metal, withstood a strain of 105,000 pounds, and broke without elongation. The knife I hold in my hand is made of this alloy. Another grade of this metal broke under an ultimate strain of 111,000 pounds with elongation equivalent to 33 per cent. It must be remembered that these tests were all made upon castings of the alloys. The strength of common brass is doubled by the addition of 2 or 3 per cent. of aluminium. Alloys of aluminium and iron are obtained without difficulty; one product was analysed containing 40 per cent. of aluminium. In the furnace iron does not seem to be absorbed readily by the reduced aluminium when copper is present; but in one experiment a mixture, composed of old files 60 per cent., nickel 5 per cent., and of "10 per cent. aluminium bronze" 35 per cent., was melted together, and it gave a malleable product that stood a strain of 69,000 pounds.

I have here a miniature anvil made of another alloy in imitation of silver; the colour is perfect, but it differs from silver in being untarnishable and very hard though tough.

This alloy is composed of aluminium, nickel and copper, as in the case of "Hercules metal," or aluminium added to German silver, and is now coming into use in America for plumbers' faucets and table knives. These latter will take any edge and hold it even to the cutting a hickory stick. I will now hand round a formidable bowie knife made from this metal. The great advantage of this metal is that it will maintain its beautiful white lustre for all time, and permits of objects being made from it like plumbers' goods and all plated ware, in an enduring and substantial manner. It requires no plating of any kind.

An aluminium and silicon bronze wire of metal made at Messrs. Cowles' works, has, I have just heard in a letter to-day, stood a testing strain of 200,000 pounds to the square inch before breaking, a tensile strength hitherto utterly unprecedented in any material.

Hitherto I have spoken of alloys of aluminium, as the experiments thus far tried to make the pure metal by this furnace direct, have not been successful. If pure alumina and carbon be used for the charge in atomic proportions, the aluminium formed still takes up carbon from the surrounding charcoal, and indeed without an excess of carbon it is difficult to work the furnace. Among the incidental discoveries

resulting from the use of this furnace are the following:—Silicon appears to have a suboxide, as in reducing silica in the furnace, if the operation be stopped before all the material is reduced, three substances are found—reduced silicon, an intermediate greenish compound and silica; the greenish compound being always found intermediate between the silicon and silica. It has not yet been thoroughly examined.

Boron has been found to make a very fine malleable bronze with copper or copper and aluminium.

Another use for this invention, and which is already exciting a large demand in America, is the manufacture of the so-called "mitis" castings, the invention of Mr. Peter Ostberg of Stockholm.

The following is a description of the process taken from an American paper:—

"The wrought-iron scrap is melted in plumbago crucibles in a special reverberatory furnace fired with petroleum. The crucible is covered, and a hole in the cover corresponds with, and is directly under a hole in the top of the furnace. Additions to the charge of the crucible are made through these holes by means of a pipe, thus avoiding the necessity of opening and cooling the furnace. Wrought-iron fuses at a temperature of say 4000 degrees Fahrenheit, and it would be necessary to heat it far beyond the point of fusion before it would be fluid enough to cast into fine moulds, and to make it possible to handle it before it would consolidate. Now it is in this superheating that the iron absorbs gases, and consequently it is impossible to make *solid* castings in this way.

"In order to obviate this difficulty, Mr. Ostberg has made use of the well-known fact that certain alloys of metals possess a fusing temperature much lower than that of the metals composing them, and among these aluminium alloys are especially notable. In making mitis castings a very small quantity, about $\frac{1}{100}$ of 1 per cent. of aluminium, in the form of a 7 or 8 per cent. aluminium alloy of cast-iron, is added to the charge (about 60 pounds) of wrought-iron in the crucible the moment this has been melted. The fusing point is at once lowered some 500 degrees, and the charge, now an alloy of iron and aluminium, becomes extremely fluid and can be cast in the finest moulds, while the great difference between its temperature and its fusing point gives all the time necessary for manipulating it without danger of its solidifying. The extreme fluidity of the charge allows the ready escape of the gases, which, otherwise, would make a porous casting, and the result appears to be a remarkably fine, solid, and tough casting of wrought-iron.

"These mitis castings are said to be from 30 to 50 per cent. stronger than the iron from which they are made.

"The alloys of aluminium and iron and steel have long been known, and reference is made to the addition of such an alloy to steel by Faraday only a few years after the discovery of aluminium; but this application to wrought-iron casting appears to be new, and it is certainly very interesting."

Now as to the ores of alumina. For mitis castings where iron and silicon are not prejudicial, bauxite and various clays can be used with advantage; for bronze making, alumina containing silica in considerable quantity is as available as the pure earth, and is indeed superior. For the manufacture of pure aluminium, pure alumina is requisite. The Cowles Company use corundum, native crystallised alumina, for this purpose; but till 1869 the sole sources of corundum were a few river washings in India and elsewhere. It was found in scattered crystals and cost from 6d. to 1s. a-pound. In 1869, however riding over a spur of the Alleghanies in Northern

Georgia, I found what turned out to be almost an inexhaustible mine of corundum in the Crysolite Serpentine, the first instance on record of corundum having been found *in situ*. It had been washed out of *débris* at Cripps Hill, North Carolina, and a mine in West Chester, County Pennsylvania, both on the slopes of the Crysolite Serpentine, before this. The clue being thus obtained accidentally, about thirty mines were shortly afterwards discovered in the same formation, but of the thousands of tons that have since been dug, by far the larger portion, I believe, has come from the Georgia mine first discovered and worked by myself.

At present the mineral can be bought at the mines at £2 a-ton. This is nearly pure alumina. A hydrated alumina, diasporé, is also found in the same region and localities. We have here sundry samples of corundum, diasporé, and concomitant rocks from the mines formerly owned by me in Georgia and North Carolina. Corundum will probably always be the principal source in America of material whereof to manufacture pure aluminium; fresh mines are being daily brought to light in the Apalachian and Rocky Mountain ranges. But in Great Britain, in all probabilities manufacturers must look to using alumina artificially prepared from cryolite or from Mr. Kynaston's sulphate of alumina. The raw materials from which the latter can be manufactured are inexhaustible. Through the kindness of the Cowles Company, I have here ingots of many varieties of bronzes, specimens of the metal as it comes out of the furnace, of carbon converted to graphite by the intense heat, of slag and of sundry articles manufactured by the Company or others from their alloys.

DISCUSSION ON MR. H. R. PROCTER'S PAPER ON TANNIN ESTIMATION, READ AT FEBRUARY MEETING.

MR. H. R. PROCTER made some observations on Simand & Weiss' method of estimating tannin by absorption with hide. This he described as an improvement on several old methods based on the same principle. In Stammer's method the sp. gr. of the solution before and after absorption of the tannin was taken. This process could be made, by great care, to give good results with gallotannic acid; but the extreme care and the time required were objections; and, moreover, for want of data regarding the physical properties of other tannins, it could only be applied satisfactorily to gallotannic acid. Weighing the hide before and after absorption was open to the objection that it was very difficult to extract all the tannin from a solution, and the same objection applied to the

evaporation of the solution and determination of the tannin from loss. Simand & Weiss have proposed to use successive small quantities of hide for the absorption, about 5 grms. being used in quantities of $\frac{1}{2}$ grm. at intervals of about 12 hours. In this way the absorption of the tannin is complete, the hide raspings give up practically no solid matter, and by evaporation of the solution very good results are obtained. The results, too, are direct, requiring no interpretation. If there is much acid present the raspings absorb it; and curiously enough the whole of the colouring matter goes down with the tannin.

Mr. B. S. PROCTOR suggested the application of hide to remove tannin from sherry used to prepare ipecacuanha wine. On keeping ipecacuanha wine it loses strength, a precipitate of tannate of emetin forming. Probably the removal of any tannin from the wine to begin with would prevent this.

Mr. Sisson exhibited an apparatus for the production and storage of hydrogen sulphide for laboratory use, consisting of a small gas-holder with a layer of paraffin oil on the water. Connected with this is a flask provided with a tap-funnel, and a siphon tube besides the gas-delivery tube. Magnesium sulphhydrate is introduced through the tap-funnel and boiled to expel hydrogen sulphide, which finds its way into the gas-holder, and can be used as required. The magnesium hydrate can be run off by the siphon tube, and fresh sulphhydrate introduced without any access of air, and thus a constant supply of pure hydrogen sulphide obtained. The apparatus is practically without smell.

ON THE USE OF MAGNESIUM SULPHYDRATE FOR MAKING PURE SULPHURETTED HYDROGEN.

BY GEORGE SISSON, JUN.

WE have only to look through chemical papers to see the various apparatus and often complicated plans which every chemist, at some time or other of his career, thinks necessary to patent and publish in order to produce H_2S with the least trouble to himself and others.

Magnesium hydrosulphide or sulphhydrate has recently been suggested as a means of producing chemically pure H_2S , and having been spoken favourably of for technical and toxicological investigation by eminent chemists, it seemed worth while to draw the attention of the Society to this new substance, which has only very lately been made on a commercial scale.

The usual method of producing H_2S is by means of ferrous sulphide and dilute HCl , or H_2SO_4 . This gives a mixture of H_2S , with hydrogen and other impurities.

For making pure H_2S it is necessary to use much more complicated and expensive methods. These are boiling sulphide of antimony, with strong HCl , and washing to separate the vapour of acid.

There are various other processes, all more or less troublesome, such as heating a hydrocarbon paraffin, for instance, with sulphur. By galvanic action of a zinc and galena couple in acid, on connecting the wires H_2S is evolved. But generally we must fall back upon sulphide of iron and acid as being the readiest and cheapest.

Two years ago Dr. Divers described a simple process for obtaining chemically pure H_2S . He passed a current of gas from sulphide of iron and acid, through magnesia suspended in water. The H_2S was more or less absorbed, and the magnesia dissolved, forming a solution of magnesium hydrosulphide,

which, on being gently heated, gave off pure H_2S , leaving the magnesia to be used over again.

The samples of hydrosulphide on the table (manufactured by the Washington Chemical Company) are not made by this method, as it was found that magnesia absorbs H_2S rather slowly, and a strong solution could not be obtained; but calcium sulphhydrate is made in the first instance, and from this is made the magnesian solution, by double decomposition with magnesium sulphate.

What answers equally well is a mixture of calcium sulph-hydrate and magnesium chloride (which is the subject of Mr. F. S. Newall's patent). In this way we can bottle and keep for a long time a solution which will give from 30 to 35 volumes of gas. The cost of the gas so produced is about the same as from ferrous sulphide and acid.

a mark is made upon the tube at the junction of the water and mercury; the piston is now lowered until the surface of the water is level with this mark, and the process repeated until the whole tube is graduated.

SAMPLING SYRINGE,

DR. TILDEN IN THE CHAIR.

ON THE SAMPLING OF VISCID LIQUIDS.

BY FRANCIS WATTS, F.C.S.

It frequently happens that it is necessary to analyse and value large quantities of viscid liquids contained in casks, etc., of varying size, the contents of each package as a rule differing in strength and value. It is obvious then that to obtain a sample which shall fairly represent the whole, a quantity proportional to the contents must be taken from each vessel; a viscid character of the liquid renders the necessary measuring somewhat difficult. To accomplish this the writer makes use of a glass syringe graduated into a convenient number of parts of equal volume; the syringe has no nozzle, but only a single round hole in the rounded or slightly pointed extremity, the size of this hole being regulated in accordance with the viscosity of the liquid to be sampled; a convenient form is one graduated in seven divisions, half divisions being indicated by a half line; in sampling a series of casks, for instance, whose sizes vary from forty to seventy gallons, each division of the syringe may be taken to represent ten gallons, or if a series of casks, varying from 100 to 130 gallons, each division might represent twenty gallons. The graduation of the syringe is easily accomplished by inverting it and covering the piston with a layer of mercury to prevent the packing absorbing water; as much water as will conveniently represent either a half or whole division of the tube is now poured upon the mercury, and the piston raised until the upper part of the tube is entirely filled with water,

In using the syringe a small air-space is left between the piston and the ascending column of liquid; this enables the operator to determine with great ease the volume of liquid drawn up: the descent of the piston effectually sweeps out the tube, leaving the syringe ready to be used in drawing the next sample.

THE SOURCES AND VARIETIES OF COMMERCIAL INDIARUBBER.

BY HUBERT PRICE.

INDIARUBBER, or caoutchouc, consists of the dried coagulated juice of various trees and shrubs belonging chiefly to the natural orders of *Euphorbiaceae*, *Moraceae*, *Artocarpaceae*, and *Apocynaceae*. The milky juice in these plants furnishing caoutchouc is contained in the middle layer of the bark in a network of small tubes called laticiferous vessels, but in the *Apocynaceae* these vessels containing the milk are also found in the inner layer of the bark. The caoutchouc is suspended in the milk in small globules about $\frac{1}{12}$ to $\frac{1}{50}$ of an inch in diameter.

The milk is coagulated by acid or saline solutions, but not by alcohol, and it is kept in the liquid state by the addition of ammonia, which is used by the collectors when the caoutchouc has to be carried long distances before coagulation. Caoutchouc

differs from other vegetable products of like origin by being insoluble in water, alcohol, alkalis, and acids, with the exception of concentrated nitric or sulphuric acids.

All caoutchouc contains an oxidised viscid resinous body soluble in alcohol; it occurs in varying quantity, the lowest percentage of this substance giving the greatest commercial value to caoutchouc.

The first mention of indiarubber in any book was nearly 500 years ago by Herrera, who, in the second voyage of Columbus, observed that the natives of Hayti played with balls made of the gum of a tree which, although large, were lighter and bounced better than the wind balls of Castile.

Torguemenda, in 1615, first mentions the name of the tree yielding caoutchouc. He says there is a tree which the Mexican Indians call "Ulequahuil"; it is held in great estimation, and grows in the hot country. It is not a very high tree; the leaves are round and ashy colour. This tree yields a white, milky substance, thick and gummy, and in great abundance.

Even at this early date the Spaniards used to waterproof their cloaks with caoutchouc, and in spite of its being used thus in 1615 by Europeans, it was not until nearly 1800 that it came into use in Europe. The indiarubber trees of South America are of the greatest importance, as they produce the largest supply. The chief of these is the *Hevea Brasiliensis*, commonly called Para, after the town from which it is exported; this tree grows to about 60ft. in height; it is of the Euphorbiaceous species; it branches from the base and has trifoliate leaves.

These trees flourish upon the muddy banks of the Amazon and its tributaries, where the temperature is never below 73° F., rain being seldom absent for more than ten days together, and in the wet season large tracts of forest are inundated. The caoutchouc is collected from August to February, which is called the dry season, but even in the dry season rain falls every few days.

The natives say that the milk flows more freely and in greater quantity in the early morning, so they start out at daybreak.

The collector at the beginning of the season goes round to the trees in his district with a stock of burnt clay cups, laying four to twelve at the root of a tree, according to its size. Footpaths are cleared, and bridges made across the streams; it is about the greatest trouble the collector meets with, as clearing footpaths through the dense undergrowth of a South American forest is a very difficult task.

When all preparations are made, the collector starts out about 3 a.m., taking with him an axe, a wicker basket containing some wrought clay, and a bag to collect odd bits of rubber. Arriving at a tree to be tapped, he takes his axe and strikes in an upward direction as high as he can reach, always striking through the bark and penetrating an inch or more into the tree, thereby damaging its growth, as the wood when exposed soon rots.

Quickly stooping down he takes one of the clay cups, putting a piece of soft clay on one side, sticks it to the bark just below the cut so that the milk will run into it. (The milk when it exudes from the tree is of a dazzling whiteness.) He then makes another cut about five inches from the last and at the same distance from the ground, proceeding as described until he has encircled the tree; he then goes on to the next tree, which he treats in like manner, and so on to other trees.

At about 1 p.m. he returns with a calabash, into which he empties all the cups, as he likes to get his outdoor work completed by 3, because that is the usual time for rain to commence.

On the following day he encircles each tree with cuts about eight inches lower down, and so on day after day until he reaches the ground.

The collectors bring their calabashes of milk to a shed where they have stored some earthen jars and a quantity of the nuts of the *Attalea* and *Euterpe edulis*, both of which are nuts obtained from palm trees; the natives say the smoke of other nuts will not answer the purpose, but I think this can hardly be the case, as the coagulation is really caused by heat driving off the water from the milk.

The milk is poured into a large flat earthen vessel placed on the floor.

The earthen jars, which are 18in. high, 12in. across the base, and 2in. at the neck, have the bottoms broken out; they are placed neck upwards on four stones on the floor, which raises them about three inches. A fire is lighted underneath them, and nuts and wood are alternately dropped into the neck of the jar until it is filled to within four inches of the top. Dense volumes of smoke now begin to issue from the neck of the jar. The collector takes a piece of wood about the shape of the paddle of a canoe, smearing a little clay over it to prevent the rubber sticking to it, dips it into the milk, lets the drops fall off, then passed it about in the smoke which issues from the jar; the milk now assumes a yellowish tinge and solidifies, but still contains much moisture. Thus the collector dips and dries until he has about an inch and a half of rubber on the mould; he then cuts it off, hanging it up to dry, proceeding with another until he has coagulated all his milk in this way. A practised hand will dry five or six pounds an hour; it is very tiring work for the arms.

All the odd bits and scrapings are made into balls about the size of a man's head, and are called negro-heads, both at Para and in the English market. Sometimes amongst the negroheads are found pieces of rubber in the form of dolls' shoes and water bottles.

The Ceara rubber is considered to rank about next to Para. It is the produce of the *Manihot Glaziovii*, a euphorbiaceous tree growing in the province of Rio Janeiro; it attains a height of nearly thirty feet, having three to seven palm-like leaves. It bears a fruit of a very delicious flavour about the size of a plum, which is much prized by the natives. The indiarubber is obtained by slicing the bark off the tree at about four or five feet from the ground; the juice exudes and flows down the stem, some reaching the ground and some drying on the tree, from which it is peeled off in strings; thus the milk of this tree is coagulated by exposure to the weather, no chemical or drying process being used.

Carthagena indiarubber comes from New Granada in sheets about three-quarters of an inch thick, having a rough chewed appearance and an almost tarry consistency. It is believed to be obtained from the *Castilloa elastica*. Guayaquil indiarubber is imported from Ecuador in large flakes of a dark colour, which are sometimes whitish when cut; it is obtained from one of the Castilloa tribe. It contains a great deal of waste.

It is curious to watch how the native mind is enlarged by intercourse with Europeans; as when a fresh source of indiarubber is found it comes first in a wonderfully pure state, but just when confidence has been obtained in the new supply, clay begins to be put into the middle of the large pieces, and as the native mind still more enlarges, all sorts of rubbish are carefully introduced, care always being taken that the impurity does not show until the piece is cut through.

Niearagua indiarubber is obtained from the

Castilloa, a lofty artocarpaceous tree with a trunk three feet or more in diameter. The leaves are eighteen inches long and seven broad. It grows in the rich fertile soils of the moist dense forests which abound in Central America. The milk is obtained by encircling the tree with a spiral cut at an inclination of forty-five feet, at the bottom of which an iron spout about four inches long is driven into the tree to deliver the milk into pails. About twenty gallons of milk are obtained from a tree four feet in diameter, every gallon of milk yielding about two pounds of indiarubber. The milk is coagulated by the addition of the juice of various herbs, about one pint of the juice being added to every gallon of the milk; the coagulum is afterwards rolled and hung up to dry for about a fortnight, when it is ready for exportation. Trees and shrubs yielding indiarubber grow throughout the equatorial regions of Africa. Mozambique is one of the best varieties. It occurs in small balls or spindle-shaped pieces called sausages; these sausages are made by taking small sticks and winding the indiarubber in thin threads round them until they have obtained the thickness and something of the shape of a pork-sausage.

Indiarubber comes from Madagascar in balls and lumps; both this and the Mozambique rubbers are obtained from the vine-like plants *Faheia Madagascariensis*, *Faheia comorensis*, *Faheia gummitera* and *Faheia Senegalensis*. The *Willoughbia edulis*, another climbing plant, is also found; it forms the chief source of indiarubber in the Mauritius. The above-named plants are all climbers, with opposite entire leaves and fleshy fruit.

In Central Africa and the east coast indiarubber is obtained from the *Landolphia Ovariensis*, *Landolphia Florida*, and *Landolphia Hendolii*. In Sierra Leone it is collected from the *Ficus brasili*, and in the Island of Reunion from the *Periploca græca*.

There are also large quantities of indiarubber imported from Asia.

Assam indiarubber is imported chiefly from Calcutta; it is glossy, and of a mottled pink colour, a little like streaky bacon. It is sent over in gummy bags in irregular masses called loaves. This rubber is the produce of the *Ficus elastica*, which is well known to you all as the indiarubber tree used for ornamenting windows; it is used for this purpose because the fumes of gas do not destroy it as they do so many other plants. It seems a curious fact, too, that by giving this plant only a potful of earth it remains alive and flourishing, with but little growth, while in the natural state it becomes a forest tree. In the forests of Assam it is the most prominent tree, the size given of a tree being 100ft. in height, 74 inches in circumference, and the crown covered an area of 610 feet in circumference. It is one of the fig tribe, and has large aerial roots. The milk is collected in the most reckless manner by making cuts about 18 inches long in the trunk and roots, from which the milk flows on to the ground. The milk is coagulated by pouring into boiling water and stirring until sufficiently firm. This is not a very good method, as if too much heat be applied to the milk before coagulation it causes a stickiness which the rubber never loses; this in the English market is called heated rubber, often not fetching more than half the usual price, and when made up into goods causes them to rapidly harden.

The *Ficus elastica* yields about 40lb. of indiarubber at 25 years, about the same amount being obtained every three years until the tree is slowly worn out by reckless tapping. Borneo indiarubber arrives in the market in shapeless masses of a whitish or pinky colour, which when cut often have a very disagreeable odour. This rubber is obtained from the

Urceola elastica *Willoughbia firma*, and *Urceola esculenta*. The former two are climbing plants, with trunks about the size of a man's body; they have a soft thick bark. The latter is a tree which at the age of five years has a stem 18 inches in circumference, and its crown covered an area of 200 square feet, which shows the rapid growth of some of the tropical trees. The milk from the climbing plants is extracted by cutting them into pieces about two feet long, which are drained into buckets and sometimes even boiled to extract the milk. The milk is coagulated by mixing with salt water, which causes the rubber to arrive here in a very damp condition, and it loses from 20 to 50 per cent. when cleaned and dyed by the manufacturer.

There are a large number of other plants which yield indiarubber, but I think I have mentioned enough to dispel the general idea that indiarubber comes from one species of tree.

Indiarubber is composed of carbon and hydrogen—87.27 per cent. of carbon, and 12.73 per cent. of hydrogen. When exposed to a temperature of 0° Centigrade it gradually loses its softness and elasticity, becoming rigid and inelastic, but may be restored to its normal condition by heating to 35°, or by stretching to twice its normal length, which takes considerable force in this rigid condition. The effects of heat are more complex than those of cold. Let us say that 15° Centigrade is the ordinary temperature, and if a strip of indiarubber be stretched by a weight and then the temperature raised to 40° C., the strip will contract, but the contracting is accompanied with a more than corresponding increase in thickness. If the heat be raised to 100° or 120° it becomes soft and loses its elasticity, but regains it when cooled. At a temperature of 150° it becomes viscous, and at 200° fairly melts, forming a thick liquid, which, when cooled, does not resume its former state. At still higher temperatures it is split into volatile hydrocarbons, leaving only a carbonaceous residue. The mixed products of dry distillation are excellent though rather expensive solvents for indiarubber. Indiarubber when pure is odourless and nearly white. The milk has a specific gravity of 1.012, but when coagulated it is .925. When freshly cut it easily unites again when pressed together.

Benzol, its homologues, carbon bisulphide, petroleum, volatile oils, chloroform, and melted naphthalene are solvents for indiarubber to a more or less degree.

It is said that if indiarubber be submitted to the action of ammonia for several months, it exerts the curious influence of bringing it back to an emulsion.

If a strip of indiarubber be stretched to about seven times its original length for two or three weeks, it loses its elasticity, and only regains it again on being subjected to heat. Possibly it takes up heat which it has lost, as when stretched it gives out a very considerable amount of heat. When in the inelastic state just described, the specific gravity rises from .925 to .9487. I will next say just a few words about the manufacture. The indiarubber, when it arrives in the crude state, has to be thoroughly cleaned from all its impurities and then dried. To effect this it is first put in large iron tanks of hot water for some hours to make it soft. When soft enough it is passed through rolls with water constantly running on them, so that when the rubber is pressed into thin pieces the dirt is washed away. This first set of rolls are not placed very close together. After it has been worked in them it is put through a close set, and after that through a set close enough to make a sheet such as I have here. These sheets are hung up in rooms heated with steam pipes, for about three weeks, and then a week in an open shed, when they are tied

up in bundles ready for use. The next process is to mix the indiarubber with sulphur and other chemicals, which is done by grinding between two rollers travelling at different speeds and heated with steam. This grinding process takes several hours. When the rubber and chemicals have been thoroughly mixed, they are passed through steel or chilled iron rollers, which have to be very smooth and true to give an equal thickness and smooth surface. These rolls are also for most goods heated.

The rubber may be fixed on cloth by passing through the above-mentioned rolls with a cloth. As the sheets come out from these rolls they are wound on to a mandril, with calico between each layer to prevent it all sticking together. These thin sheets are then in various ways made into different articles as required. The rubber at this stage is in a soft state and can be pulled in pieces and stuck together or pressed into any shape by means of an iron mould. When made into the shape required by moulding or other ways, it has to be vulcanised. This is done by heating the indiarubber with sulphur intimately mixed with it. The exact action is not known, but it seems to most nearly resemble the change of iron into steel. Some have said that it takes an allotropic form. It is said that two per cent. is about the right amount of sulphur to use, but manufacturers use from 5 to 12 per cent. Only a small proportion of this is really chemically combined with the rubber; the rest remaining intimately mixed with it, and causes the process of vulcanisation to slowly go on, especially if exposed to heat; this causes the indiarubber to become brittle.

The effect of the sulphur seems to cause a setting of the sticky and resinous portion of the indiarubber, giving it greater elasticity, and destroying its stickiness and power to be cut in pieces and stuck together again. If a large quantity of sulphur be added to indiarubber, when vulcanised it becomes quite hard, and under the name of vulcanite or ebonite, is used to make combs, paper knives, and many surgical instruments. The black colour of vulcanite is also curious, as before vulcanisation it appears grey in colour, but when vulcanised and polished it is jet black. Vulcanite has not much elasticity, breaking when bent sharply. It resists solvents more pertinaciously than ordinary rubber. A great variety of stiffness may be obtained in indiarubber by adding different amounts of sulphur, from a billiard cushion to a vulcanite ruler.

The process of vulcanisation was discovered by Goodyear, an American, who after a great number of experiments hit on this by accident.

A Mr. Parks invented a method of cold vulcanisation. He dips the article to be vulcanised in 100 parts of sulphuret of carbon, and $2\frac{1}{2}$ parts of protochloride of sulphur, for a few minutes, then he immersed the indiarubber in cold water. This method will only vulcanise a thin substance of rubber.

The usual way vulcanisation is carried out by manufacturers is by placing the goods to be vulcanised in a long iron tray, filled with French chalk, which is pressed tightly over the goods. The tray is then run along a tramway into an iron cylinder, made of boiler plate, ends are then securely screwed on, and the steam is turned into it. Different manufacturers use different pressures, varying from 60lb. to the square inch to 15lb. The time the trays are left in the boilers, of course, depends on the heat and the amount of sulphur in the goods. It runs from 7 hours to 5 minutes, and for some special articles it takes days.

Various attempts have been made to manufacture a substitute for the actual caoutchouc, which will cut out the natural product, but at present they have not been attended with very satisfactory results. Many

articles are sold for rubber substitutes, and a good deal is used to mix with the genuine article, as no very satisfactory result has been obtained when they are used alone. Of course, when mixed with rubber they deteriorate the quality, but they keep the goods light, without adding to the cost, and the adulteration is almost impossible to detect by analysis. The ordinary substitutes, such as I have here, are made of castor oil and chloride of sulphur.

Dr. Fleming has a patent substitute, which he uses for insulating purposes, without any native india-rubber, but it is not a success. It is made by taking some substance, as wood cotton or straw, and dividing it very finely, then saturating with melted bitumen or asphalt, incorporated with silicate of magnesia, lime, iron or alumina; then mix in amber resin or kauri resin, heat to 250 per cent., and mould into shape required under pressure.

Harrison's substitute consists of Agar-Agarseaweed, dissolved in acetic acid, then add cowrie gum, pistacia gum, castor oil, and Stockholm tar; stir and boil till consistency of treacle, then cool, roll and dry.

Zuighi makes a substitute by dissolving half-a-cwt. of cowrie gum with an equal quantity of manilla gum, in 5 gallons solvent naphtha, adds 2lb. of camphor and 5lb. of aluminous matter, heats to 250° F., then adds 20 per cent. of native rubber, and treats in a masticator with 10 per cent. of castor oil.

Hoffman's substitute is made by boiling skins of bares and rabbits in water, with 5 per cent. of glycerine, evaporate to dryness, add an equal quantity of glycerine, and 1 part of concentrated solution of bichromate of potash. It is then heated and poured into moulds, and hardened under pressure. There are also many other mixtures used, but none come any way near the native article.

Most substitutes contain a certain amount of acid, which causes a rotting of the cloth they are spread on.

The electric macintoshes lately so much in vogue, contain a large quantity of substitutes, and the process by which they are made has the curious effect of sending some of the employes out of their minds.

Many people seem to think that red rubber is better than grey, but the colour is no check on the quality, as it is only obtained by the addition of pentasulphide of antimony, vermilion oxide of iron, or other colouring matter.

I will not now add more to this paper.

ON THE USE OF TURMERIC AS AN INDICATOR FOR CITRIC ACID.

BY FRANCIS WATTS, F.C.S.

WHEN litmus is employed as an indicator in the alkalimetric determination of citric acid, some difficulty is experienced on account of the want of sharpness in the indications; citrates of potash and soda being slightly alkaline to litmus, the results obtained are frequently too low. To remove this difficulty, Warrington, in his Notes on the Chemistry of Tartaric and Citric Acids, * recommends the preparation of a special litmus paper, but even with this precaution the difficulty is not entirely overcome. I have found the following method give good results. A tincture of turmeric is prepared with strong spirit, drops of this are placed on a white tile, or better, in the depression of an ordinary colour slab. The liquid spreads out in bright yellow films; drops of the solution being tested are from time to time placed on these yellow films. As the addition of the alkali proceeds, the slightest excess of alkali causes the

development of the well-known red-brown colour. This indicator can be used in the cold, and also works well in the analysis of concentrated lemon or lime-juice, the red-brown colour being readily seen even in the presence of the dark liquids which have to be dealt with in these cases, in which the delicate pink of phenolphthalein (which has been recommended as an indicator of citric acid) is scarcely visible.

In order to test the delicacy of tincture of litmus as an indicator, the following experiment was made: About three grains of citric acid were nearly neutralised with caustic soda and carbonate of barium added in excess; the mixture was boiled and filtered. The filtered and boiled solutions did not cause the development of a pink colour with phenolphthalein, neither did it change the colour of the yellow turmeric film; litmus paper, however, was turned decidedly blue by it.

A faint pink colour was developed in phenolphthalein by the addition of less than .0015grm. NaOH, a strong pink colour being caused by the addition of .0025grm. to the above solution.

With turmeric a slight change was noticed when .0028grm. NaOH had been added, and a decided change with .0042; this latter quantity produced a sufficiently deep red to have been noticeable with dark solutions. When this last solution was diluted to five times its volume (being originally 20cc.) the red-brown colour was still developed on adding a drop to a turmeric film. It will be seen that much greater certainty arises from the use of this indicator in the place of litmus.

In using this indicator much time is saved by employing litmus paper to determine the near approach to neutralisation, proceeding with the addition of the alkaline solution until the litmus paper is turned slightly blue, and determining the exact point of neutralisation by means of the turmeric. In the case of unconcentrated lemon and lime-juices the change of colour of the juice when nearly neutralised renders the employment of litmus paper unnecessary.

Note.—I am indebted to the kindness of the Montserrat Co., for permission to publish these notes; the experiments on which they are founded being conducted in their West Indian Laboratory.

ON THE FERMENTATION OF CITRIC ACID.

BY FRANCIS WATTS, F.C.S.,

*Chemist to the Montserrat Company (Limited),
Montserrat, W.I.*

WARRINGTON* has made an attempt to ascertain the amount and nature of the volatile acids in concentrated Sicilian lemon-juice with a view to determine the acids, other than citric, to be found in lemon-juice. Now when perfectly fresh lime-juice is distilled, the distillate is neutral, and consists only of water, with a little essential oil derived from the peel. It is thus clear that volatile acids are not normal constituents of the juice, and some explanation of their presence seems necessary.

When lime-juice is allowed to stand for some days in an open vessel, a film of mould gradually forms upon the surface; this, when examined under the microscope, is found to consist of numberless cells of *saccharomyces mycoderma*.† If juice which has

been in this condition for several days be now distilled, the distillate is found to be acid. 1000cc. of such juice were submitted to distillation, 200cc. being first collected. This acid distillate was now rendered alkaline, and again distilled to separate any alcohols that might be present. The alcoholic distillate was mixed with a little sulphuric acid and bichromate of potash, gently warmed, and finally distilled, yielding a distillate having an acid reaction. The very small quantity of acid thus obtained only permitted a superficial qualitative examination. On the addition of nitrate of silver only a very slight reduction took place on warming. Ferric chloride in neutral solution gave a very decided red colouration. An attempt was made to identify propionic acid in the mixture by means of the basic lead salt, but owing to the small quantity of material only equivocal results were obtained. From these reactions we may infer the presence of acetic acid, a minute trace of formic acid, and possibly some propionic, and indirectly the existence of ethylic alcohol, with possibly some propylic and minute quantities of methylic alcohols, in the original juice after fermentation.

The residue from which the alcohols had been distilled was mixed with a second distillate of 200cc. from the original 1000cc. of juice, very nearly the whole of the volatile acids being thus collected. This liquid was then neutralised with caustic soda, and concentrated; on the addition of ferric chloride the red colouration indicative of acetic acid was obtained. The addition of other reagents gave no decisive results, though it seemed probable that some propionic acid was present.

In order to determine the presence of ethylic alcohol in the fermented juice, 500cc. were submitted to distillation, the product carefully rectified, and C_2H_5OH sought by means of the iodoform test; only a very slight precipitate of iodoform resulted.

From the above examinations it was evident that very slight quantities of volatile acids or alcohols resulted from the changes experienced by the juice in keeping.

The residue resulting from the distillation of the 100cc. of juice was now rendered alkaline with caustic potash and again distilled, and a liquid strongly alkaline with ammonia passed over. In order to detect any alcohols resulting from the decomposition of citric ethers, the alkaline liquid was neutralised with hydrochloric acid, the alcohols distilled off, warmed with a small quantity of chromic acid mixture, and finally distilled. A feebly acid distillate was obtained, which gave no red colour with ferric chloride in neutral solution. Oxide of lead in excess was added to the distillate; the resulting basic lead salt of the volatile organic acid was soluble in water, so that probably propionic acid was present (basic butyrate of lead is insoluble). From this it may be inferred that some citric ether is present, that it is not ethyl citrate, but is probably propyl citrate in very small quantity.

Having thus found that volatile products (other than CO_2) are not formed in any quantity by the development of this *saccharomyces* in the liquid, experiments were now undertaken to prove that citric acid is not split up into other non-volatile acids.

Experiment I.—For this purpose a quantity of freshly-pressed lime-juice was set aside for the mould to develop, and the free acid and citric acid determined at intervals.

Experiment II. was conducted on juice from un-soured fruit, fermentation being promoted by the addition of juice containing mould. The results of the analysis are given in the subjoined tables and

* Journal Chem. Soc. October, 1875.

† Messrs. W. Southall and W. B. Grove very kindly undertook the further examination of this fungus for me. My own observations induced me to think that at least two distinct varieties existed. Grove, however, seems inclined to consider the different forms observed as transient phases in the life of this very variable fungus. The point for the present remains undecided.

diagrams. The free acid is stated in terms of citric acid. Before the sample was withdrawn for analysis the juice was thoroughly stirred up. This may have made the action of the fungus slightly irregular.

The determination of the citric acid was conducted in the manner recommended by Warrington (*loc. cit.*):—

EXPERIMENT I.

Day.	* Free Acid per cent.	Citric Acid per cent.	Citric Acid per 100 of Acidity.
1	8.72	8.40	96.32
4	8.62	8.33	96.63
7	8.36	8.20	99.16

Now, if other acids were formed at the expense of the citric acid, it is at once evident that the proportion of citric acid to total free acid would become smaller and smaller, and the curves in the diagram diverge as the fermentation proceeded; this, however, is not the case.

The loss of citric acid is not, therefore, attended by the formation of volatile substances (CO_2 excepted), nor of non-volatile acid. That non-volatile neutral bodies are formed to any appreciable extent does not seem very probable.

Stoddart states ("Pharmacographia," art. "Lemon-juice"), that when lemons had been kept six months the citric acid was largely converted into grape-sugar. Only slight reduction of Fehling's solution took place when mouldy lime-juice was boiled with it, corresponding to about .1 per cent. $\text{C}_6\text{H}_{12}\text{O}_6$.

In order to examine the effect of the growth of the fungus in citric solutions free from saccharine and gummy matter, a solution of citric acid was mixed with the bodies necessary to plant life (in reality, Pasteur's solution, with citric acid substituted for sugar and tartaric acid). This solution was then seeded with a little "cultivated" *saccharomyces mycoderma*, free from bacteria and other bodies which are largely associated with it in natural juice. As the development of the mould proceeded, carbonic acid was given off, though no bubbles of gas escaped from the liquid, the gas being gradually evolved from the film of mould. When the fermentation had so far proceeded that 15 or 16 per cent. of the citric acid had disappeared, a portion of the solution was distilled; the distillate was perfectly neutral, and consisted of water only—no alcohols could be detected. The citric acid was now removed from a portion of the solution, as calcium salt, and an attempt made to examine the residue for neutral bodies; but the liquid soon swarmed with bacteria, and became putrid, so that the examination had to be abandoned. The volatile bodies found in the examination of natural juice after fermentation must therefore be due either to the presence of saccharine matter or to the action of other ferments—most probably to the combined effects of both.

It has been shown that no other acid than carbonic is formed during this process, and also that no volatile bodies are produced; it now remains to be proved that no non-volatile compounds are formed.

A solution containing 2.2080 grms. of dried citric acid ($\text{H}_3\text{C}_6\text{H}_5\text{O}_7$) and .1278 grm. of mixed mineral matter necessary for the support of vegetation in each 100cc. was prepared. Of this solution 200cc. were set aside to ferment, and sown with a small quantity of *saccharomyces*; at the end of fifteen days the film of mould contained, in addition to the *saccharomyces*, a patch of *penicillium*, and also of *aspergillus*; the liquid was filtered and made up to 200cc.; on analysis this was found to contain 1.408 grms. dry citric acid per 100cc. Of this liquid 150cc. were evaporated to dryness in the water-bath, and the residue maintained at a temperature of 100°C ., until the weight became constant; it yielded a residue weighing 2.2527 grms. Now, assuming for the moment that the mineral matters in the solution had remained unaltered, the theoretical weight of the residue for 150cc. would be as follows:—

Citric acid	2.112 grms.
Mineral matter.....	.1917 "
	<hr/> 2.3037 "

instead of which we have the weight 2.2527, which is deficient by .051 grm., a portion of which deficiency is probably due to the removal of mineral matter in the mould. This result proves most conclusively that no non-volatile body is produced during the fermentation. It will be noticed that 36.36 per cent. of the citric acid, originally present, was lost by fermentation in fifteen days.

Determination of the Rate of Loss in Equal Volumes of Citric Acid Solutions, with different areas exposed to the Action of Saccharomyces Mycoderma.—A solution containing suitable mineral matters with 5.48 grms. of citric acid $\text{H}_3\text{C}_6\text{H}_5\text{O}_7 \cdot \text{H}_2\text{O}$ per 100cc. was prepared. Of this liquid three separate lots of 250cc.

little saccharomyces mycoderma. On the 18th day the solutions were analysed—the volume lost by evaporation being made up by distilled water. The loss in the case of *a* was 8.87 per cent. of the original acid; *b*, 17.89; *c*, 33.57. From this it appears that the loss of acid is not directly in proportion to the

EXPERIMENT I.

EXPERIMENT II.

each were set up in vessels having the following relative areas exposed to the air and the action of the mould—*a* area exposed=1, *b* area exposed=4.38, *c* area exposed=8.26; each solution was sown with a

area exposed to the air and mould; for, taking the loss in the case of *a* as unity, we have—

Areas of exposure... *a* 1, *b* 4.38, *c* 8.26
Loss of acid = 1, = 2 = 3.4.

This variation is probably due to movements in the fluids, successive particles of the solution coming in contact with the mould.

From these experiments, then, it is evident that, under the influence of *saccharomyces mycoderma*, citric acid is split up directly into carbonic acid and water, oxygen being absorbed. It was found that the growth of the mould ceased shortly after air was excluded. This is simply in accord with the general law, that ferments forming a mycelium and floating on the surface of a suitable fluid, oxidise and split up the substances on which they act into simple carbonic acid and water.

The Sixth Meeting of the Session was held in the Rooms, 207, Bath Street, on Tuesday, 6th April, 1886.

J. M. CUTHBERTSON, ESQ., IN THE CHAIR.

ON ALGINIC ACID AND ITS COMPOUNDS.

BY E. C. C. STANFORD, F.R.S.

MANY of the compounds which I propose to bring before the Section this evening were exhibited in London last year at the Inventions Exhibition, and a lengthened notice of these by Watson Smith was published in our Journal last September. These products have never been described, and had only then been prepared and shown for the first time. In consequence, however, of that notice, I have been overwhelmed with inquiries, many of which I have been unable to answer, from all parts of Europe and beyond it.

These inquiries have assured me of the great publicity which the Journal of this Society gives to any information appearing in its columns, and have also led me to believe that considerable interest is taken by many of its readers in these new substances.

I propose, therefore, briefly to describe the most important, and to indicate their composition so far as my investigations have hitherto extended. Considering the general character of these compounds, I think it will be admitted that the analytical results are extremely satisfactory.

The starting-point in the preparation of all these compounds is insoluble algin, or alginic acid. I have

fully entered into the manufacture of this substance in a former paper, and need not further allude to it here.

Alginic Acid is a nitrogenous organic acid. As first precipitated it forms a light-brown gelatinous precipitate. When reprecipitated it becomes nearly colourless, and can be obtained perfectly white. The precipitate, when well washed, is extremely retentive of water, taking up over 98 per cent. In this form it is somewhat difficult to deal with, as it cannot be pressed, although it is easily filtered off; and, as might be expected with such a body, it is impossible to completely wash out the salts and obtain it free from ash. It dries up to a horny substance resembling albumen, and has then a specific gravity of 1.534; that of the ivory nut is 1.376. It can be turned and polished in the same manner. It is easily obtained in thin transparent sheets, which possess considerable tenacity. In this form it is an efficient substitute for bladder in tying over pots and bottles; it softens in water and becomes pliable in the same way, and it dialyses equally well. It can be readily coloured as shown in the red and blue samples on the table. In this form it resembles coloured sheets of gelatine, but unlike these is unaffected by hot water. It is a moderately strong acid, evolving carbonic acid in the cold from the alkaline carbonates, and from magnesium carbonate. I must leave the consideration of several interesting decompositions of this substance for a future paper, but subject to any further light which any of these may ultimately throw on its constitution, I append what I believe to be the formula. This was derived from two combustions of a carefully-purified specimen; and the figures obtained accord with the formula $C_{38}H_{40}NO_{11}$.

	1.	2.	Mean.	Calculated.
Carbon	65.151	64.80	64.977	64.985
Hydrogen	5.667	5.80	5.734	5.700
Oxygen	24.762	25.16	24.961	25.020
Nitrogen	2.117	1.94	2.028	1.995
Ash	2.300	2.30	2.300	2.300
	100.000	100.00	100.000	100.000

Subsequent analyses of the alginates, however, have led me to the conclusion that this formula must be doubled, and that the true composition of the acid is $C_{76}H_{80}N_2O_{22}$; or it may be expressed as a diamide—

There appears to be a remarkable relationship between this body and albumen. If we accept Gerhardt's formula for albumen, $C_{72}H_{112}N_{18}SO_{22}$, and deduct from it the sulphamide, N_2H_4S , which Mulder assumes it to contain, and then deduct also 14 molecules of amidogen, NH_2 , it leaves the formula $C_{72}H_{80}N_2O_{22}$, which only differs from alginic acid by 4 atoms of carbon. Whether the process can be reversed, and albumen built up from algin remains to be seen; it would be a very important synthesis, and many more complicated and more difficult have been accomplished. It bears no relation to the ordinary vegetable pectin compounds, even if it were non-nitrogenous, the formula of pectin being $C_{32}H_{48}O_{32}$, and that of pectic acid $C_{16}H_{22}O_{15}$. Albumen is a very weak acid, acid or soluble sodium albumenate, $C_{72}H_{111}NaSO_{22} + H_2O$, contains only

1.66 per cent. Na. It is singular that the insoluble albumenate contains more soda. The general formula of the alginates I take to be $C_{7.6}H_{7.7}M_3N_2O_{2.2}$, although there are some important differences from this type.

Soluble Alginates.—The soluble alginates are those of sodium, potassium, ammonium, lithium, and magnesium.

Sodium Alginate.—This salt is the ordinary soluble algin; analogous to soluble albumen. It is best prepared by acting on moist alginic acid by sodium carbonate. The properties of this soluble alginate have been already described; the most remarkable reactions are, that it is at once coagulated by nearly all acids, or by alcohol, but not by acetic acid, nor by heat; that it does not gelatinise; that it precipitates all the alkaline earths except magnesium, and all the metals except mercury as mercuric chloride. It is usually obtained in thin sheets, which are soluble in cold water, forming a very gelatinous solution. It takes some time to dissolve, and is therefore washed from any vessel containing it with difficulty.

This solution may be employed as a general dressing or finishing material of an elastic flexible character, which can be converted into a lustrous hard glaze by passing it through a weak acid or lime salt. This process, which would destroy the ordinary starch and gum dressings, renders it quite insoluble in water, the fabric becoming waterproof.

Sodium alginate gave by analysis 8.04 per cent. Na. The following formula requires 7.75 Na = 23:— $C_{7.6}H_{7.7}Na_3N_2O_{2.2}$.

This alginate has an acid reaction, and is an acid alginate, and represents the least proportion of sodium necessary to render it soluble. The same remark applies to the other soluble alkaline alginates, all of which have an acid reaction, and the base in each salt is not saturated. The probability is, if quite neutral, there would be at least six atoms of the metal present. I have little doubt of this, but it is not yet conclusively proved; and in all the following analyses the figures are corrected for the extraneous matter impossible to eliminate.

The alginates of the other alkali metals resemble that of sodium in general properties, the different bases presenting advantages in some applications.

Potassium Alginate gave by analysis 12.51 per cent. K.

The following formula requires 12.49 K = 39.1:— $C_{7.6}H_{7.7}K_3N_2O_{2.2}$. It is prepared by acting on moist alginic acid by potassium carbonate. Reaction, acid.

Ammonium Alginate gave by analysis 5.65 per cent. NH_3 . The following formula requires 5.84 NH_3 = 17:—

It is prepared by dissolving moist alginic acid in ammonia. It combines with a number of metallic alginates and other bodies, which will be further alluded to presently. Reaction, acid.

Lithium Alginate gave by analysis 2.30 per cent. lithium. The following formula requires 2.49 per cent. Li = 7:— $C_{7.6}H_{7.7}Li_3N_2O_{2.2}$. It is prepared by acting on moist alginic acid by lithium carbonate. Reaction, acid.

Magnesium Alginate gave by analysis 4.18 per cent. Mg. The following formula requires 4.20 per cent. Mg = 24. $Mg_2(C_{7.6}H_{7.7}N_2O_{2.2})_2$. Reaction acid. This remarkable body is prepared by acting on moist alginic acid in the cold with magnesium carbonate or oxide. In the former case carbonic acid is abundantly given off, and the two insoluble substances combine to form a dense colourless solution, which dries up to a film, closely resembling that of sodium

alginate, but it is more brittle, and forms a stiffer dressing for fabrics.

Insoluble Alginates.—Some of the metallic alginates are very soluble in ammonia. I will refer, in the first instance, to those which are insoluble in that alkali. In most of these compounds the metal can be dissolved out by hydrochloric or other strong mineral acid, leaving the alginic acid unchanged. The metals may replace a greater or less number of atoms of hydrogen than those given in the formula, so that the exact constitution of these salts is not yet absolutely determined, but all are calculated on the same basis; and the results are fairly consistent.

Barium Alginate is a dense white gelatinous precipitate prepared by acting on calcium chloride with sodium alginate, both in solution.

Analysis gave barium 23.02 per cent.

The following formula requires Ba 23.17 per cent.

Calcium Alginate is a white gelatinous precipitate prepared by acting on calcium chloride with sodium alginate, both in solution.

Analysis gave calcium 7.84 per cent.

The following formula requires Ca 7.66 per cent.

This substance hardens into hard solid white blocks, which take a good polish. In this form calcium alginate has a specific gravity of 1.609; that of ivory is 1.82. It can also be prepared in transparent flexible sheets.

Lead Alginate is a transparent colourless gelatinous precipitate, obtained by precipitating lead acetate with sodium alginate.

Analysis gave, by reduction, lead 30.8 per cent.

The following formula requires 31.29 per cent.

Bismuth Alginate is a dense white gelatinous precipitate obtained by precipitation from bismuth nitrate by sodium alginate solution.

This substance has not yet been examined.

Mercurous Alginate.—Sodium alginate has no action on mercuric chloride, which distinguishes it from albumen. Mercurous alginate forms a dense white gelatinous precipitate, and is obtained by the action of sodium alginate on mercurous nitrate, both in solution.

It is blackened by ammonia.

This substance has not yet been examined.

Insoluble Alginates, which are soluble in ammonia. All these form double salts, or ammonia alginates, some of which present beautiful films. The bases are masked, and do not present the ordinary characteristic reactions.

Strontium Alginate is a dense white gelatinous precipitate formed by precipitating a solution of strontium chloride with sodium alginate.

Analysis gave strontium 15.51 per cent.

The following formula requires Str 16.10 per cent.

$Str = 87.5 \quad C_{7.6}H_{7.7}Str_3N_2O_{2.2}$. The precipitation is not so well defined as in the other alkaline earths. This substance is remarkable for its solubility in ammonia. Strontium ammonio-alginate forms a white tenacious film insoluble in water.

Aluminium Alginate forms a white gelatinous precipitate, obtained by precipitating aluminium sulphate in solution by sodium alginate.

Analysis gave aluminium 6.40 per cent.

The following formula requires Al 6.59 per cent. $Al = 27.5 \quad Al_2(C_{7.6}H_{7.7}N_2O_{2.2})_2$. The proportion here is abnormal, as in many aluminium compounds. This substance is soluble in caustic soda, and the solution evaporated forms an excellent film resembling that of sodium alginate, but stiffer; it is very soluble in water, and would form a cheap and efficient glaze for paper or cloth. It is quite neutral.

Aluminium alginate is very soluble in ammonia, forming aluminium ammonio-alginate, which becomes insoluble when dry. It will form a cheap water-proof varnish. Alumina is completely removed from solution as alginate; not a trace can be afterwards found in the liquid. The alumina can be completely separated from an acid solution of redonda phosphate as alginate. The gelatinous character of the precipitate makes it a good mordant or dung substitute; adhering to the cloth and not easily rubbed off.

Copper Alginate is a green gelatinous precipitate, obtained by precipitating cupric sulphate by sodium alginate in solution.

Analysis gave copper 12.20 per cent.

The following formula requires 12.25 per cent. $\text{Cu} = 63.5 \text{ C}_{7.6} \text{H}_{7.7} \text{Cu}_3 \text{N}_2 \text{O}_{2.2}$. A combustion was made of this salt, but by an accident only the hydrogen was estimated correctly. The formula requires H 4.937. The analysis gave H 4.92. This compound is very soluble in ammonia, forming a beautiful deep blue solution of cuprammonium alginate, which dries to a bright green film, insoluble in water.

Analysis of this salt gave copper 16.98 per cent.

Ammonia (NH_3) 6.58 per cent.

The following formula would require $\text{Cu} 17.51 \text{ NH}_3 6.64$ per cent. $\text{C}_{7.6} \text{H}_{7.7} \text{Cu}_3 \text{N}_2 \text{O}_{2.2} + \text{Cu}_2(\text{NH}_3)_7$.

One or more atoms of NH_3 have probably been lost on evaporation; but this compound requires further investigation, and I only give a suggested formula. This substance may be useful as a varnish, especially for waterproofing fabrics which are liable to decomposition or to attacks of insects. Cuprammonium solution cannot be obtained stronger than two to 2½ per cent. of copper, and cannot be preserved if it contains more than 1.5 per cent. of copper. This compound contains eight times as much of the metal, and it is soluble in water in almost any proportion before drying.

Nickel Alginate is a light green gelatinous precipitate, prepared by precipitating nickel chloride by sodium alginate in solution.

Analysis gave nickel 11.49 per cent.

The following formula requires 11.42 per cent. $\text{Ni} = 58.6 \text{ C}_{7.6} \text{H}_{7.7} \text{Ni}_3 \text{N}_2 \text{O}_{2.2}$.

It is soluble in ammonia, forming a beautiful blue solution which dries to a brilliant green film, insoluble in water.

Cobalt Alginate is a light red gelatinous precipitate prepared by precipitation from cobalt nitrate solution with sodium alginate.

Analysis gave cobalt 11.35 per cent.

The following formula requires Co 11.42. $\text{Co} = 58.6 \text{ C}_{7.6} \text{H}_{7.7} \text{Co}_3 \text{N}_2 \text{O}_{2.2}$.

It is soluble in ammonia, dissolving to a bright red solution, which dries to a dark red film insoluble in water.

Ferric Alginate.—Ferrous sulphate yields no precipitate with sodium alginate, but if the slightest trace of a ferric salt be present, a reddish-brown gelatinous precipitate of ferric alginate is obtained.

Analysis gave iron 10.92 per cent.

The following formula requires 10.97 per cent. $\text{Fe} = 56 \text{ C}_{7.6} \text{H}_{7.7} \text{Fe}_3 \text{N}_2 \text{O}_{2.2}$.

Iron is so completely precipitated by sodium alginate that not a trace can be found in the filtrate by the most sensitive colour test.

Ferric alginate is soluble in ammonia, forming a deep red solution, which on evaporation affords a dark red film insoluble in water. This substance is likely to become useful in surgery as a styptic for wounds, and in medicine as another means of administering iron internally.

Zinc Alginate.—A colourless gelatinous precipitate formed on precipitating zinc sulphate by sodium alginate.

Analysis gave zinc 16.06 per cent.

The following formula requires 16.05 per cent.

$\text{Zn} = 65 \text{ C}_{7.6} \text{H}_{7.7} \text{Zn}_4 \text{N}_2 \text{O}_{2.2}$.

It will be observed that like the aluminium salt, the proportion of zinc is abnormal.

Zinc alginate is very soluble in ammonia, affording a colourless solution of zinc-ammonium alginate, which dries to a brilliant transparent film, insoluble in water. This solution may be employed for the same purposes as cuprammonium alginate; and substituted for it where the colour is an objection.

Cadmium Alginate, made by precipitating cadmium nitrate by sodium alginate, resembling the zinc compound, and is equally soluble in ammonia, the solution on evaporation giving an opaque white film, insoluble in water. This substance has not yet been examined.

Manganese Alginate is a colourless gelatinous precipitate obtained by the addition of sodium alginate to manganese sulphate in solution.

It is soluble in ammonia, forming a brown solution which dries to an olive-brown film, insoluble in water. This compound is still under investigation.

Chromium Alginate is a blue gelatinous precipitate, made by precipitating solution of chrome alum with sodium alginate. It is soluble in ammonia, forming a blue solution, which dries to a brilliant olive-green film insoluble in water. This substance is under investigation.

Sodium alginate mixed with a bichromate is sensitive to light in the same way as gelatine, the mixture becoming insoluble in water after exposure to light.

Uranium Alginate is a yellowish-brown gelatinous precipitate prepared by precipitation from uranium nitrate solution with sodium alginate. It is very soluble in ammonia, forming a deep yellow solution, which dries to a brilliant yellow film, insoluble in water. It may be useful as a varnish for optical purposes. This substance has not yet been examined.

Platinum Alginate is a brown gelatinous precipitate obtained by precipitating platinum chloride solution with sodium alginate. It is very soluble in ammonia, forming a yellow solution, which dries to a yellow film, insoluble in water. This substance is under investigation.

Silver Alginate.—The silver salt, usually pretty definite, is not so with alginic acid. It can scarcely be called an insoluble salt, as it is only precipitated in concentrated solutions, and even then incompletely. It is a colourless gelatinous precipitate, very sensitive to light and very soluble in ammonia, the solution drying to a dark reddish-brown film, which on exposure to light becomes a brilliant silver mirror, the metal being reduced on the surface. It ought to have some applications in photography, but its properties have not yet been investigated.

Tin.—*Stannous Alginate* is a white gelatinous precipitate obtained by precipitating stannous chloride with sodium alginate. It is very soluble in ammonia, forming a colourless solution, drying to a transparent film, insoluble in water.

Stannic Alginate is a white gelatinous precipitate obtained in the same way from stannic chloride. It is also very soluble in ammonia, forming a colourless solution, drying to an opaque white film, which is soluble in water.

Arsenic Alginate is a colourless gelatinous precipitate made by precipitating arsenic chloride with sodium alginate. It is soluble in ammonia, forming a colourless solution, which dries to an opaque film, quite soluble in water.

Antimony Alginate is a dense white gelatinous precipitate obtained by precipitating antimony chloride with sodium alginate. It is soluble in ammonia,

forming a colourless solution, which dries to a transparent film, soluble in water.

This and the three preceding alginates are under investigation.

Shellac Algin.—Shellac is soluble in alkalis, and therefore combines with the alkaline alginates. Any of these may be employed, but I have found the shellac ammonium alginate the best. A solution of ammonium alginate, combined with one-third of its weight of shellac, forms a light brown solution, which dries to a tenacious film, quite soluble in water. When this film is passed through a bath of weak hydrochloric acid it becomes insoluble, the alginic acid and the shellac being deposited together. A flexible sheet is thus formed having considerable strength, and much resembling sheet gutta-percha, which for some purposes it may replace, as, for instance, in bandages and dressings. Looking at the great brittleness of shellac, which destroys its value for many applications, no one would suspect its presence in such quantity in this very pliable sheet. Solutions of calcium or aluminium or other such salts may be used for the bath, and in these cases the resulting film will be a combination of shellac with calcium or aluminium, or other alginate.

It is obvious also that many other resinous substances, of which shellac is only an example, may be incorporated in a similar manner with a soluble alginate and then rendered insoluble.

Compounds of algin may also be obtained by precipitating an insoluble alginate with an insoluble phosphate, borate or silicate, giving a large range of new compounds.

Alginic acid also combines with many alkaloids, forming soluble films resembling those of ammonium alginate. Some of these may be useful in medicine, but I cannot say more about these bodies this evening, because none of them have been yet fully investigated, and because this paper has already obtained sufficient longitude, and perhaps latitude, for one evening.

The bodies of alkaloidal character which have been prepared and are on the table, are the alginates of quinine, aniline, chinoline, and toluidine, in reference to which I may have something to say on a future occasion.

DISCUSSION.

The CHAIRMAN said there was hardly one of the new substances mentioned that was not full of interest and suggestion. He would like to ask, firstly, if cotton could be dyed with aniline colours after being mordanted with algin; and, secondly, whether films—either of algin or its ammonium compounds—might be used as a photographic substratum to hold sensitive silver salts?

Mr. COLEMAN could fully endorse the Chairman's remarks. It seemed to him that very remarkable results had been obtained in making soluble, by the action of alginic acid, precipitants which were ordinarily insoluble. He would be glad to know whether any experiments had been made on the technical applications of algin compounds. He also looked forward to the author receiving some remuneration for the vast amount of labour he had given to the subject.

Mr. CHRISTIE said that twelve months since he had made some fairly successful experiments with a view to substitute alginate of soda for cow-dung in fixing alumina upon cotton goods, though at first he had found it difficult to prepare a salt which would completely precipitate the alumina. The author now told them that alginic acid was capable of forming soluble double salts with metals and ammonia, the corresponding simple metallic salts being insoluble.

It occurred to him (Mr. Christie) that instead of printing acetates and sulphates of alumina upon cotton cloths, and afterwards fixing them by alginate of soda or other dunging agents, the soluble ammonium and aluminium alginate might be used at once for printing, and the ammonia afterwards driven off by heat; thus avoiding a long and costly process, and yet obtaining the alumina in a suitable condition for dyeing. If he could be furnished with some of that soluble aluminium and ammonium salt, he would like to try it, and would report upon it at a future meeting.

Mr. FULTON asked whether, in precipitating a solution of redonda phosphate by algin, the alumina alone would be separated, or whether iron alginate would go down with it. He regretted that during that portion of the paper relating to iron salts of algin he had been so occupied in examining some of the specimens that he had missed the point in question. The specific gravity of algin had been stated to be little less than that of ivory; he would be glad to know how the two substances compared in regard to elasticity?

Mr. STANFORD, in reply to the Chairman, said that as yet he had not been able to investigate the relations between aniline colours and algin compounds in regard to cotton, but might mention that the blue sheets of alginic acid on the table were coloured by Mulhouse blue. In regard to photography, he had already mentioned that though the silver salt of algin was very sensitive to light, yet it was by no means definite, and in addition was partially soluble in water. In photography, algin would more probably be employed with bichrome in the same way as gelatin, over which it had certain advantages.

With regard to the precipitation of aluminium alginate from a solution of redonda phosphate, it should be remembered that the advantage of algin over other precipitants was that alginic acid only acted on aluminium in an acid solution. It would, in all probability, also bring the iron down with it.

As regards elasticity, no doubt sheets of algin were very elastic, but he had not yet tested the material in blocks.

Mr. Christie had made a very valuable suggestion as to the employment of aluminium alginate dissolved in the first place in ammonia, and afterwards rendered insoluble, and care should be taken to supply him with large samples for his experiments. The fact was that he had been quite unable to meet the demands upon him for this substance up to the present, though in two or three months he trusted that he would be able to satisfy everybody.

ON THE ACTION OF POTASH ON RESINS.

BY EDMUND J. MILLS, D.S.C., F.R.S.

MOST resins consist in the main of one or more acid bodies, capable of taking up bromine, and also capable of acting upon potash in such a way as to form saline compounds. Bromine absorptions for all the principal resins have been previously published (*Journal*, 1885, 96); in the present paper, a series is given of potash absorptions.

The method of determining the potash absorptions was as follows:—A suitable quantity of the finely-powdered resin was introduced into a stoppered bottle, having a capacity of about 100cc., and a decided excess of normal alcoholic potash was run in. The bottle having been closed, was well shaken, and then allowed to stand for about eighteen hours. In many cases, however, such prolonged contact was not really necessary, but for the sake of uniformity it

was adopted in every case. When the specified time had elapsed, a little phenol-phthalein was added to the liquid, and the titration was completed with the aid of normal hydric chloride in the ordinary manner. At least two determinations were made in each case. The following table contains the results. It includes, also, a column of bromine absorptions for the same samples, and the calculated numerics of the resins on the suppositions that they are pure and monobasic. These suppositions are very nearly correct in the case of good rosin, but, probably, only approximately so in the other cases:—

POTASH ABSORPTION OF RESINS.

RESIN.	Potash %	Bromine %	Numeric.
Rosin, refined	18.10	112.70	308.62
Shellac, bleached	18.20	161	306.92
„ not bleached	23.01	5.21	242.76
Gum, Benzoin	22.31	38.90	—
„ Amber	16.07	53.53	347.60
„ Animé	9.54	60.22	585.51
„ Gamboge	15.47	71.56	361.09
„ Copal	12.39	[89.93]*	450.85
„ „ reduced to $\frac{1}{4}$ by boiling	12.89	[84.52]*	433.36
„ Sandarac	16.40	96.42	340.61
„ Kauri	12.88	108.22	433.70
„ Thus	21.03	108.51	265.62
„ Dammar	5.23	117.91	1068.07
„ Elemi	3.29	122.23	1697.87
„ Mastic	11.67	121.33	478.66

* Determined on other samples.

From the above table it appears that, in a few cases, the potash absorption is inverse to the bromine absorption; but, on the whole, there is evidently no systematic connection between them.

The action of alcoholic potash takes place very easily with the following resins—viz., rosin, lac, benzoin, thus, elemi; easily with kauri and mastic; less readily with the rest. Rosin, lac, animé, sandarac, thus, and mastic dissolved completely or almost completely.

The potash absorption, considered by itself, exhibits a feature of singular interest. If we arrange its values in arithmetical order, they fall into seven well-defined groups. (See table on next column.)

[In these groups, common shellac and gum benzoin do not appear, on account of their containing decided amounts of non-resinous bodies.] The potash absorptions are clearly multiples by a whole number of a fundamental constant nearly equal to 3. It may be theoretically deduced from that of pure rosin ($C_{20}H_{30}O_2 : KHO = 18.492$ p.c.) by dividing by 6, which gives 3.082 for the value of the constant. From this number the above calculation has been made; and it evidently agrees with experiment. It may be otherwise calculated by dividing the experimental potash absorptions by 1, 2, 3, etc., and taking the most probable value of the resulting quotients; the deduced constant is 3.075. It is evident, then—whatever the proximate composition of the natural resins may be—that they are in effect a series of polymers of a body $C_{20}H_{30}O_2$, a formula that does not admit of further division. The proximate composition has, in fact, been in many cases partially

examined, and the constituent resins are invariably found to correspond closely in their formulae with such polymers. Great stress, it is true, cannot be laid upon the results of these examinations. Alcohol and alcoholic potash,—the discriminating agents chiefly employed,—are not likely to leave entirely unchanged a resin with a high numeric, and there may be some natural oxidation; indeed, the whole subject requires, and would well repay, an ample revision. What can be alleged with much certainty is, that the natural resins are, *in effect*, a simple series of polymeric substances.

Group.	Resin	Potash, per cent.	Potash, per cent. cal.

MIXTURES OF RESINS.

The qualitative analysis of resins, like the qualitative analysis of oils or fats, leads to hardly any satisfactory result. Questions of this kind are best approached from the quantitative side. I have, therefore, thought it worth while to ascertain whether, in a mixture of resins, the potash absorption is altered in proportion to the amount of admixture.

Experiment I.—A mixture of equal weights of bleached lac, animé, and dammar was made, and its potash absorption found to be 11.05 per cent. The mean of the three experimental numbers is 10.99 per cent.

Experiment II.—Equal weights of bleached lac, boiled copal, and dammar were mixed, and the mixture absorbed 11.72 per cent. of potash. According to the table the percentage should be 12.11.

VARNISHES.

The numbers adduced in this paper will prove of value in the analysis of varnishes, an operation which sometimes presents almost insurmountable difficulties. The volatile solvent—such as ether, alcohol, turpentine—is easily determinable by simple evaporation with water; driers can usually be estimated after ignition. Most of the problems are due to the resins.

The following experiments show that the potash absorptions of a resin is not altered in presence of boiled oil.

Experiment I.—A sample of boiled oil was titrated with alcoholic potash in the cold, and found to take up 3.22 per cent. A sample of pale French resin absorbed, on gentle heating, 18.15 per cent. A solution was prepared containing 25.46 parts of resin in 74.54 of boiled oil; a blank experiment for loss was simultaneously performed upon the boiled oil, the temperature not being allowed to exceed 120°. The boiled oil in the blank experiment lost 3.35 per cent. Allowing for this and acidity, the potash absorption

in the cold (in presence of a little ether) was found to be 18.76 for dissolved resin.

Experiment II.—A similar experiment was carried out with a mixture of 87.92 parts boiled oil, and 30.68 parts of boiled copal (potash absorption, 11.44 per cent.). The absorption for the dissolved gum was found to be 11.64 per cent.

It is evident that boiled oil, when heated with a resin, makes no alteration in the resin's acidity.

Let us consider a case in which we have removed the volatile solvent from a varnish, and have to deal with a residue containing only two resins and boiled oil. Such a residue is perhaps the one that most frequently occurs. First, to a portion of it add enough ether for solution, or nearly complete solution, and at once titrate in the cold with alcoholic potash; this gives the potash absorption due to the resins. Secondly, to another portion add excess of alcoholic potash, cohobate as in an ordinary saponification experiment, cool, and titrate; this gives the potash absorption due to all three constituents. If r , c , and b be the respective weights of the first and second resins, and of boiled oil in a gramme of the residue, α , β , and γ , the potash absorption per gramme of these substances respectively; P , the potash absorption of one gramme of the residue before cohobating, and Q after cohobating, we shall have—

$$\left. \begin{aligned} 1 &= r + c + b \\ P &= \alpha r + \beta c \\ Q &= \alpha r + \beta c + \gamma b \end{aligned} \right\}$$

Hence

$$\left. \begin{aligned} b &= \frac{Q - P}{\gamma} \\ r &= \frac{\beta(1 - b) - P}{\beta - \alpha} \\ c &= 1 - b - r \end{aligned} \right\}$$

It is assumed that the boiled oil has no acidity. If there is reason to suppose that it is acid, 1 per cent. of potash may be taken as an approximate allowance.

In the important case of a varnish containing rosin (r) and boiled copal (c), the value of α is .1848, of β .1232, and of γ (deducting 1 per cent. for acidity) .1875. The equations become—

$$\left. \begin{aligned} b &= 5.3333 (Q - P) \\ r &= 16.234 \left\{ P - .1232(1 - b) \right\} \\ c &= 1 - b - r \end{aligned} \right\}$$

The results thus obtained may be checked by accurately determining the specific gravity of the varnish, and calculating it from the analytical data. There should be a fair agreement. An error of 1 per cent. in the allowance for acidity of boiled oil corresponds (in a residue containing one-third of it) to an error of 1.76 per cent. in that residue. The error will be proportionately less on the varnish, and is, therefore, not of any great importance.

The following data are necessary in calculating the specific gravity, at 15°, of a varnish containing boiled copal, rosin, boiled oil and turpentine.

Specific gravity of dissolved boiled copal	1.073
rosin	1.075
boiled oil (apart from driers)935
turpentine864
litharge.....	9.363

If a decided amount of litharge be present in the form of linoleic soap, it must be determined and multiplied by the factor 3.1868, in order to calculate the amount of soap. As this soap has no potash absorption, its weight must be deducted from the residue before calculating the weight of C from the equation last given. If other driers have been used, suitable corrections must be similarly made for them. I have obtained good results by this method.

DISCUSSION.

MR. STANFORD was very much surprised to see this sample of sylvic acid, and to understand that it could be obtained so easily and directly from resin. It was very remarkable, and he would like to ask Prof. Mills how many crystallisations from alcohol were necessary to obtain the acid in a pure state?

Prof. MILLS, in reply, stated that two or three crystallisations were sufficient, provided the resin was very old, as new resin crystallised very slowly indeed.

PROFESSOR CLOWES IN THE CHAIR.

FILTRATION AND WATER SOFTENING.

BY P. A. MAIGNEN.

THE impurities in water may be divided into two classes—namely, those in suspension and those in solution. To remove the suspended matters on the large scale, sand alone has stood the test of time. It is a very rough filtering medium, but it has the advantage of being cheap. Without entering into details of the composition of the sand beds made by the water companies, suffice it to say that the filtration obtained in this way is but partial. It cannot remove all the finest suspended impurities, such as the specific germs of typhoid fever, as was unfortunately shown in the case of the Bangor epidemic. The frequency of diarrhoea in hot seasons is in great part owing to this defective system of filtration. Domestic filtration was until a few years back considered a delusion and a snare, and many scientific and sanitary authorities have been profuse in their condemnation of domestic filters. For it must be remembered that if a filter does the work for which it is intended, that of retaining the impurities of water, these must be removed periodically, or they contaminate the water instead of purifying it. It is a notorious fact that domestic filters of the old types were constructed on the principle “of giving no trouble to the users,” “of being self-cleansing,” or “of not requiring any attention for years.” The worst defect of these old-fashioned filters is that they contain portions which are cemented or otherwise sealed down; and fixed filtering media, such as charcoal blocks, porous stone or clay, the inside pores of which cannot be cleansed without rendering the filter perfectly useless.

The next point of importance, in speaking of filters, whether for domestic or industrial use, is efficacy.

Among the suspended matters in water there are very small inorganic particles, and some living micro-organisms which are smaller still. These can only be removed by a filtering medium which is finer than, or at least as fine as, the impurities themselves. Sand does not possess that quality, neither does coarse charcoal; the voids between the particles of the filtering medium are too large to arrest the microscopical impurities. We say nothing of sponges, wool, or similar organic matters, as they are known to decompose rapidly, and to be either too expensive for constant renewal, or insufficient to purify water. Charcoal blocks, porous stones, or biscuit china have fixed pores, which are either too large, and allow the water to pass too freely—or too small, when the water does not pass at all, or passes in too small quantity; moreover, the action of these media is purely mechanical; while none of these filtering media are capable of arresting more than a trace of matter in solution.

Whilst speaking of the purity of the filtering medium, I would point out to chemists one valuable use they can make of my invention. When ordinary filtering papers are used in funnels, they have to be washed with weak acids to remove impurities. By my process the filtering paper is reduced to a pulp, washed until no impurity remains in it, and then it is used so as to make on the filtering surface, as it

FIG. 1.

were, a thick piece of paper felt. Thus not only is a pure filtering material formed, but also a very effective filter; wherever there is a pore larger than another, a floating particle of paper, following the current, goes to mask the pore, and then the filtering layer is even and equal everywhere. The materials which I employ for the filtration of water are—

I. Pure asbestos cloth.

II. A filtering material which consists of finely-powdered well-burnt animal charcoal, the soluble matters of which have been extracted with weak acetic acid. After repeated washings it is boiled in lime-water; this not only clarifies the water, but also removes organic matter and metallic salts in solution. The filter is very easy to cleanse.

Fig. 1 shows a section of these filters at work. R is the reservoir for the filtered water. It is accessible for cleansing, as the filter-case proper

simply rests loosely on it. M is the filtering frame covered with asbestos cloth E, tied with asbestos cords. D is a layer of powdered charcoal, deposited automatically by being mixed with the first water poured upon the filter. C is granular charcoal put in loosely to fill all the available space between the layer of the powdered material and the screen B.

The water being put into the filter, passes first through the granular charcoal, then through the layer of powdered charcoal, and lastly through the asbestos cloth, issuing into the hollow filtering-frame M in a most minute state of division, and it falls perfectly pure and aerated into the reservoir R. It will be seen that this new filter differs entirely from anything which has ever been introduced before, and that the water is not only purified, but also oxygenated, and rendered brisk and pleasant to drink.

About every six months, in this country, the filtering medium should be removed and replaced with a new charge. Now it should be observed that, unlike purely mechanical filters, this exerts an absorptive and chemical action, as is shown by water contaminated with sewage being rendered perfectly pure, as judged by the permanganate test; lead, copper, zinc, and iron are also removed, and claret is turned into a colourless liquid. This may be explained by the action of the oxygen gas condensed in the pores of the charcoal, which not only oxidises the organic matter, but also the metallic bases of the dissolved salts, forming insoluble oxides which are arrested mechanically. The peculiar smell which is found in the liquid obtained from claret is indicative of an aldehyde, proving that the alcohol has been oxidised.

You will observe that not more than one inch of the granular charcoal is above the layer of the powdered charcoal in the filter on the right, whilst as much as six inches of the same material are in the filter on the left; but in this latter filter there is no asbestos cloth nor powdered charcoal. Yet the first *does* arrest dissolved impurities and the second *does not*. This proves what we have urged at the beginning of this paper—that a granular or coarse filtering medium alone is incapable of filtering water properly.

I proved long since that a thin layer of fine material is more efficacious in purifying water than a thicker layer of coarser material. Sir Frederick Abel, at the conclusion of the Conference on Water Supply at the International Health Exhibition, after alluding to the various methods of water purification, said:—“With regard to other methods of purifying water, considerable improvements have been effected in recent years in the application of filtering media—such, for instance, as charcoal preparations in a more or less finely divided condition. . . . There could be no doubt that the action of charcoal as a purifying agent, quite apart from its action as a simple filtering agent, was much promoted by constantly renewing the surface of contact between the charcoal and the water, and so he would imagine that filtering on the principle devised by M. Maignen would act more efficiently and rapidly than the mere passage of water through charcoal *en masse*.”

We have seen that the finest impurities in suspension, organic matter in solution, nitrates and nitric acid, also metallic salts in solution, are removed by filtration through our filters (and as far as we are aware by no other filtering medium), but as we said at the beginning of this paper, something more is required to remove the dissolved earthy salts. All water which contains more than seven grains of mineral matter per gallon is considered *hard*. The substances which render them hard are commonly carbonate of lime and sulphate of lime. The suitability of a very hard water for drinking purposes is questionable, but it is undoubtedly unsuitable for

washing purposes. The loss of soap owing to this cause in London alone is estimated at half-a-million sterling yearly. About two pounds of soap is wasted for every 100 gallons of water used in washing. When soda or washing powders are introduced in the washing tub, a certain economy of soap is effected, but a considerable deposit is precipitated on the linen. By softening the water previous to its use, not only is there a much greater saving, but the linen is better washed, and not damaged in any way. The salts of lime and magnesia thrown out of solution by soap or soda, interfere with the weaving and dyeing operations.

It is, perhaps, in steam boilers that the greatest troubles have been experienced. No less than 160 substances have at different times and in different places been introduced into boilers to prevent the formation of scale. Some of these substances convert the lime salts into mud instead of hard crust, but they do not get rid of the mischief, and in many cases they introduce evils greater than those they are designed to palliate. The water ought to be softened *previous to its use*, and not inside the boiler.

Many attempts have been made to soften water; but the only process which has stood the test of time is that of Professor Clark, who, in 1841, discovered that the addition of lime-water to hard water produced the same effect as boiling—that is, it drove out of the bicarbonate of lime the excess of carbonic acid which was holding the salt in solution, and the simple insoluble carbonate of lime or chalk was precipitated. This process only affects the bicarbonates, and being unable to remove sulphate of lime, must be accounted an imperfect one.

My process, which is intended to remove this imperfection, was very clearly described by Mr. Baldwin Latham, C.E., in his paper read at the Conference on Water Supply, held at Kensington during the International Health Exhibition. (See *Society of Arts Journal*, August 15, 1884, vol. xxxii. p. 927.)

I have combined in *one powder*, the three reagents,

Quicklime,
Carbonate of Soda,
Alum,

in proportions which vary according to the composition of the water to be softened. This is prepared in a very finely powdered and anhydrous state, and it is introduced into the water either by hand or by an automatic apparatus. On introducing this powder into the water, the lime acts on the bicarbonates in the same manner as in Clark's process, with this difference, however, that the trouble and expense of making lime-water is saved, and the exact quantity of lime which is required to produce the desired effect is employed. Whilst the carbonates are thus thrown down by the lime, the carbonate of soda dissolves, and removes the sulphate of lime by double decomposition, precipitating the lime as carbonate, and leaving sodium sulphate in solution. For a water like that of London, which has a hardness of 15°, about 18 grains of the powder per gallon are used. This is equivalent to one ounce for twenty-five gallons.

For softening large quantities of water, either one or more tanks large enough to hold twelve hours' supply are required, so that the water may have an absolute rest of a few hours to clarify itself after it has been softened; or a complete softening plant, which consists of an automatic feed-apparatus, softening and settling tank, and filter, may be employed. The powder is put daily or weekly, as the case may be, in the hopper G. As the water comes in through the ball-tap E, it rises over the water-wheel F in B. The motion thus given to the wheel starts a mill in the hopper, which delivers, through a

regulating door, the exact quantity of powder that is necessary to produce the degree of softness desired. Thus, if the water comes in fast, the powder falls fast into the water, and *vice versa*.

FIG. 2.

The chemical action is complete in about one hour, and when it cannot be allowed to settle by itself, which would be a matter of a very few hours, a filter may be used to arrest the suspended matter. This process is found to be very simple and easy of application.

DISCUSSION.

The CHAIRMAN said that there were many interesting points in the paper they had just heard, several of which were well worthy of discussion. The meeting would have the advantage of hearing the opinions of some of those present who were experts on this subject. The "Filtre Rapide" seemed to have one great recommendation, viz., that it could be easily cleansed by heating the asbestos cloth and renewing the charcoal.

Mr. M. O. TARBOTTON asked how far the system could be applied on a large scale. Water treatment came under two heads—purification and softening. Science had laid down a course of treatment to secure the former, but the latter presented many difficulties. Nottingham water varied in hardness from 7 to 22 degrees, one-fourth of which was permanent. Waters up to 16 degrees of hardness were not unwholesome to drink: but for manufacturing purposes a soft water meant a saving of about 2½ lbs. of soap for every 100 gallons used. He himself was quite satisfied with Clark's process, but should like to make himself further acquainted with the one before them.

Mr. JOHN HARDISTY asked if the author could give them an estimate of the cost of his process on the large scale, such as for softening "feed" waters, comparing it with other processes per given "indicated horse power"! He would also like to know whether soft water drinking caused softening of the teeth and bones?

Dr. HANDFORD said that nearly all waters contained sufficient earthy constituents to maintain the teeth and bones; but hard waters were apt to cause gastric derangements. In Glasgow and Liverpool there had been a marked improvement in this respect in the public health since they had acquired a soft supply. The process before them did not claim to remove magnesia, salts, and chloride of calcium, yet these were among the most objectionable constituents of potable water—"goitre" had been attributed by some to drinking water impregnated

with lime-salts. It certainly was prevalent in some limestone districts. For instance in Oude, on granite and gneiss, 2 per cent. of the population were affected; on mica slate and hornblende rather more; on clay slate, 5·4 per cent.; on green sand, none; while on limestone, 33 per cent. suffered from the disease. In Switzerland, "goitre" was common where neither magnesia nor lime-salts abounded, and seemed most prevalent where iron pyrites and metalliferous rocks were present. As to domestic filters, many medical men objected to them *in toto*, because it was impossible to ensure their being constantly cleansed; and because it was considered that the public ought to be able to depend on the purity of their water supply without being asked to purify it themselves. The filtration of water on a large scale was a different matter, and well worthy of consideration. Dr. Percy Frankland had for some months past daily examined, by the new gelatin process (see *Journal*, Dec. 1885), the water of one or two of the London Companies, before and after filtration. He found that large sand-filters diminished the number of living spores from 80 to 90 per cent. Spores lived in pure water, and might pass through a filter which would stop bacteria. Did, however, these filters stop bacteria?

Professor BLAKE noted that the author claimed for his apparatus the power of separating particles of organic matter. But could it also deal with the organic matter in solution?

M. MAIGNEN said that he would show by experiments that it could.

Mr. J. B. COLEMAN took exception to the statement that the lime in the softening mixture acted first, for were not the alum and soda more soluble? They had better omit the alum if its only use was to hasten precipitation. In Dublin, where a softer supply of water had recently come into use, there was an undoubted increase of defective teeth among the children.

Mr. R. LLOYD-WHITELEY said that the meeting should have been furnished with more explanations as to the uses of the various constituents of the softening powder, especially as to the alum. As far as he could see, the mixture would be just as good without it. What they wanted was some practical means of softening large quantities of water for manufacturing purposes.

Dr. WHITELEGGE asked what was the amount of organic matter and the number of organisms in solution before and after the process? The author should also have given more details as to the amount of solids removed by his filtration process. The removal of lead ought not to be left to the haphazard chances of domestic filtration; and a water supply containing ever so small a proportion of that metal ought to be condemned for drinking purposes. Where also the supply was soft and likely to take up lead from the fittings, special precautions should be devised to prevent danger from such a source; but if people would only run to waste the first water they drew in the morning, there would be an end to lead poisoning. In Sheffield, however, they were trying the experiment of adding a little lime to harden the water in their reservoirs, so that there would be less chance of its acting on the fittings. The Nottingham supply was so good that domestic filters were unnecessary, but he thought that there was room for them in outlying villages where the quality of the supply was very bad. As to the relative merits of hard and soft waters, he thought that a moderately hard water did no harm, and it certainly had the advantage of being palatable. The so-called "chalky" deposits, characteristic of gout, contained neither lime nor carbonic acid, but consisted mainly of urate of soda.

Would the author offer some explanation of his statement that his filter removed permanganate of potash from solution in water? It seemed almost incredible.

Mr. W. J. ABEL said that so long as the disease germs were removed from water that was all that was necessary to secure a wholesome supply, but Dr. Frankland's experiments went to show that filtration did not completely accomplish this.

Mr. LEWIS T. WRIGHT said that "goitre" was often attributed to drinking snow water. In London there were two classes of water drunk—deep well water and river water. If one was hard, the other was under suspicion of contamination, so that it was merely a choice of evils.

M. MARGEN, in reply, said that he could hardly explain all his results; he could only say that such results did occur. He had letters from firms who had been using his process for their "feed" waters, and their experience was that no scale whatever was formed on the boilers. It was true that they might not want his filters in Nottingham, but there were plenty of country places where they would be of great use. Surely if his filtration process would remove the colour of claret, it would remove spores and germs.

Mechanics' Institute, March 6.

PROFESSOR CLOWES IN THE CHAIR.

SOME NOTES UPON DYED HOSIERY AND ITS RELATION TO SKIN IRRITATION.

BY JOHN R. ASHWELL.

Introduction.—The fact that "blood poisoning," or "skin irritation," has been stated to be caused by wearing dyed hosiery next the skin, is one which some people in Nottingham and the neighbourhood have from time to time seriously to combat. To most people the subject is of interest, I venture to think, because they have worn dyed hosiery for many years without experiencing any ill effects. I have been asked to lay before you to-night some of the points which should be understood and carefully considered before any charge of skin irritation is preferred against dyed hosiery. Probably no fabric is so universally worn next the skin as hosiery, and there are some conditions attending the dyeing and finishing of hosiery which I believe are without any parallel in the case of other dyed fabrics. At the outset, let me be clearly understood what is meant by the term "dyed hosiery." This term *is not* meant to cover such hosiery fabrics as are made from dyed yarns; but it *is intended* to cover such coloured hosiery fabrics as have been dyed *after being manufactured*. The limitation is important.

Its effect is to remove from our notice some of the highest qualities of hosiery, of which the quantity is small, and being made from dyed cotton or wool yarns, are distinguished frequently by two or three fine stripes of white cotton or wool at the welt, as well as by a white toe and heel; or which are made from dyed cotton or dyed wool yarns wrought into stripes, etc. These yarns are dyed throughout England, whilst "hosiery dyeing" is a trade carried on in a very limited area around Nottingham and Leicester.

It will be my endeavour to-night to lay before you some of the principles involved and materials employed in dyeing hosiery. I shall endeavour to accomplish this on broad, general lines, avoiding detail, and grouping colours together according to the mordants and dyestuffs employed. It will also be

necessary for us to form some idea of the condition in which the dyes exist upon the fibres, as well as those conditions which obtain when hosiery is worn.

1. *Dyed Hosiery*.—The main bulk of dyed hosiery consists of fabrics made of wool, cotton, and mixtures of wool and cotton known technically, and according to quality, as "merino," and as "shoddy." The chief points to be desired in dyed hosiery are—(1) cleanliness in wear; that is, neither staining the skin nor underclothing; (2) resistance to washing; that is, the colour should be capable of resisting such combinations (cold or hot) of soap or alkali *which the laundress chooses to employ*; (3) permanence of colour; that is, the colour must keep in stock for two or three years without material alteration in colour; (4) the dye must not materially interfere with the elasticity and softness of the original fabric—four conditions with which very much of the dyed hosiery does not comply. Without doubt, dyed wool hosiery complies the most completely. Mixed wool and cotton, or merino hosiery, complies far more completely than does cotton hosiery; although some colours on cotton leave but very little to be desired.

Among the colours applied to hosiery fabrics there is a noteworthy absence of mineral pigments, produced by the precipitation of hydrated metallic oxides or of metallic salts—*e.g.*, manganic oxide, chromate of lead or manganese, Prussian blue, copper arsenite, etc. Possibly the only exception is that of ferric hydrate, and even this is never used as a self-colour. The insoluble red woods—barwood, camwood, etc.—are not employed when fabrics have to be dyed, although used upon unspun fibres which find their way into hosiery. All colours which possess very slight resistance to light and soap are avoided in self-defence by the dyer.

2. *Mordanting Cotton Hosiery*.—With but very few exceptions, almost the whole of the cotton hosiery is subjected to a mordanting process; indigo-blues and some light shades dyed by the "stuffing and saddening" method are the chief exceptions. The mordanting process consists in impregnating first with a solution of some tannin matter, and afterwards with an excess of a solution of some metallic salt. By this means an insoluble tannate is obtained within the fibre, and serves as a mordant for the various colouring matters subsequently applied. Before the colouring matters are applied, the mordanted fabric containing an excess of the soluble metallic salt is subjected to a very severe process of rinsing, in which cold water and friction are combined. The water removes the soluble metallic salt, whilst the friction is necessary to remove any loosely adhering precipitates, such as form on diluting a solution of stannous chloride, or which "hard" waters form with many solutions of metallic salts.

Tannic acid, galls, sumac, black and cube cutch, together with various extracts, are largely employed as tannin matters. Ferrous sulphate, crude ferrous acetates, various "nitrates of iron," stannous and stannic chlorides, stannate of soda, cupric sulphate alum, and bichromate of potash are the most largely employed metallic salts. The insolubility of the metallic tannates and their adherence to the fibres are both, of necessity, very complete, in order to withstand the combined action of friction and cold water. These two conditions are of importance when the possible absorption of the tannate as a whole, or in part, by the skin is considered. In self-defence, the dyer errs on the side of over-rinsing his goods before dyeing, in order to secure a level colour, etc.

The tannates of tin and iron, alone or combined, form the mordant upon which almost all colours dyed upon cotton hosiery may be produced. Tannates of tin are used as mordants for bright reds, wine colours,

light and dark blues and greens, and many light bright colours obtainable from "basic" anilines, either with or without dyewoods. This use of tannate of tin upon cotton hosiery dates from a period which is far beyond the recollection of any now in the trade.

It is found that such a "tannate of tin," as it exists upon dyed cotton hosiery, is decomposed by alkaline perspiration. The perspiration becomes acid, gives a precipitate with gelatine, becomes dark coloured on standing, and behaves as if tannic acid had passed into solution; but such a solution contains *no trace* of tin. Tannate of tin, as it exists in dyed cotton hosiery, has stood the most searching test of time and experience in wear; so that it is most difficult to see how any charge of skin irritation can be laid against it.

Tannate of iron is very largely used for the production of blacks with logwood. Its use for this purpose upon hosiery is old. It has stood the test of time and experience in wear; and when we remember M. Bousingault's figures (*Compt. Rend.* 74, 1355—1359), estimating the quantity of iron taken daily by a man in food and drink at from 0.591 to 1.09 gm., it becomes difficult to see how insoluble salts or oxides of iron may be justly charged with skin irritation.

"Double tannates of tin and iron" are used for the production of dark colours from various "basic" anilines. A much-used process is to mordant with tannate of tin, rinse, dye with the "basic" coal-tar colour, and then darken with some salt of iron.

In actual practice, almost all colours in which "basic" anilines are employed, may be produced by judicious mordanting with tin or iron tannates, or both. This being so, I shall take a few colours which typify the whole, and deal with them in detail.

3. *Dyeing Cotton Hosiery: Browns*.—Almost all browns, from light tans to dark seal-browns, upon hosiery, are derived from cutch or gambier. Dark seal-brown, which is fairly typical of these colours, is produced as follows:—The hosiery is "poled" in a hot bath of cutch, cupric sulphate, and logwood, lifted, and put through hydro-extractor; then treated with a hot solution of bichromate of potash, and afterwards with a salt of iron, or the iron-salt may precede the use of bichromate of potash. These operations are repeated as a whole, or in part, till desired shade is obtained. Such processes were not in use for hosiery dyeing before 1850, although well known in other departments before that date. Colours produced upon hosiery by such methods vary far less than a mere analysis of ash would indicate. The first table on page 228 gives four analyses of ash from different dark seal-browns upon cotton hosiery. These give an average of 17.45% Cr_2O_3 , 15.400% Fe_2O_3 , and 19.75% CuO , calculated upon the weight of unburned hose.

Cotton hose dyed seal-brown become weighted, and thereby the softness and elasticity of the fabric become diminished.

In the ordinary process of washing by a laundress the colour is reduced in depth, and much of the oxides present is removed. I have known test-cases where goods (without being worn) having been washed ten times with soap, without addition of alkali, will lose 5.35% in total weight, including 93.76% of CuO , 18.49% of Fe_2O_3 , and 25.13% of Cr_2O_3 present upon unwashed hose. Such losses during careful but severe washing are significant, and I hope at some future time to give other and more extended figures. However, the length of time—thirty-five years—during which such colours have been dyed upon hosiery, as well as the enormous quantity yearly produced, gives great force to the conclusion that these colours cannot be called skin irritating.

Blacks.—The methods for dyeing black upon cotton

hosiery vary very greatly, although the materials employed upon the great bulk vary very slightly. Tannate of iron is the mordant upon which large quantities are dyed with logwood, with very rarely an addition of some old fustic. Sometimes cupric sulphate is used after dyeing with logwood, in order to get certain effects. Tannin matters, such as galls, sumac, cutch, are sometimes used upon better-class

greens or wine colours the principles employed are pretty much the same. The mordanted goods are dyed by machinery with a suitable mixture of "basic" anilines, rinsed in cold water, dried, and then soaped. Logwood is sometimes used along with or after the "basic" anilines, and then a little alum is used. Sometimes goods are treated with a solution of tannin matter after dyeing with the "basic"

WEIGHT OF HOSE.	Cr ₂ O ₃	Fe ₂ O ₃	CuO.	REMARKS.

blacks, and frequently such blacks are "bottomed" with indigo. Where cutch is used, cupric sulphate and bichromate of potash are also employed, as well as some iron-salt and logwood. Frequently the dyeing operations are repeated, in order to obtain greater solidity in appearance, as well as durability of colour. The following are five analyses of ash from black cotton hose:—

anilines; this is useful in making the colour faster.

The coal-tar colour used may be divided, *for our purposes*, into two classes. (1) Those in which arsenic is employed in the manufacture, *e.g.*, Magenta. (2) Those in which arsenic is not used.

Under the term "Magenta" I include Magenta proper and those residues variously known as cerise,

WEIGHT OF HOSE TAKEN.	Fe ₂ O ₃	CuO.	REMARKS.
55·748grms.	1·0826grms. = 1·942%	none	The first two have an indigo "bottom," the others have not. The better qualities are at the top, and the poorer qualities are lower.
52·351grms.	·902grm. = 1·7229%	none	The better qualities have more tannin and less log- wood upon them than the poorer qualities.
46·180grms.	·559grm. = 1·215%	none	
47·612grms.	·4859grm. = 1·025%	trace	
51·273grms.	·5188grm. = 1·012%	·0527grm. = ·102%	

These give an average of 1·383% Fe₂O₃.

The metallic oxides are largely removed by mere process of washing with soap. I have known 32·92 per cent. of the iron oxide present, so removed by washing ten times without ever being worn; but as the black was common in quality the colour was greatly reduced.

Colours in which Coal-tar Dyes are employed.—For light and bright shades tannate of tin may be employed, but for darker shades the "double tannate of tin and iron" is much used. The dyewoods employed are logwood, and sometimes old fustic. For blues and greens, varying from sky to navy blue, or peacock to myrtle green, the following colouring matters find most demand:—Ethylene and methylene blues, indulines, benzylated rosaniline violets, together with methyl green and benzaldehyde greens. For wine colours varying from bright reds to claret the following find most demand:—Magentas, Safranines, Methyl Violets, Bismarck brown, and Auramine. Whether it is desired to produce bright or dark-blue

Grenadin, "Aniline brown," Maroon, etc., which contain more or less Induline and Phosphine in addition to Magenta.

To admit the presence of Arsenic in Magenta is popularly equivalent to saying that Arsenic exists in hosiery dyed with Magenta. So far as dyed cotton hosiery is concerned, nothing is further from fact, and as to woollen hosiery, so little Magenta of either kind is used for hosiery fabric dyeing that it may be ignored. In 1872 Dr. Springmühl ("Die Chemische Prüfung der Künstlichen Organische Farbstoffe") gives fourteen analyses of magenta for arsenic; the arsenic then found varied from 6·5 to 0·25 per cent. During the past six years it has not been my lot to meet with "magentas" containing more than ·237 per cent. of arsenic, and the average of several analyses shows ·0804 per cent. As. A magenta largely used in dyeing contains ·021 per cent. of Arsenic. Cotton hose mordanted with tannate of tin, rinsed, dried, soaped, and redried do not, on analysis, show the slightest inclination of arsenic (for the method em-

ployed see *Chemical News*, xliii. p. 21); the weight of cotton hose taken for analysis was 95·631 grms.

These hose for analysis were taken from a lot weighing 68 lb., and were fairly representative of an ordinary dye. It must, however, among other conditions, be remembered that the machinery and methods employed for rinsing and soaping hosiery are far more efficient than those used in ordinary experimental dyehouses. Such facts, which might be greatly amplified, justify me in saying that in dyeing hosiery with magentas, it is a difficult thing to fix arsenic upon the hose by an ordinary process of dyeing and finishing; indeed, it is rarely achieved.

Among the other "Aniline" colours used in hosiery dyeing, the absence of spirit-soluble blues and violets, and of those blues which are sulphonates of a substituted rosaniline base, are noteworthy. Various circumstances preclude the use of these colours in dyeing hosiery.

Of the blues, violets and greens which are in use, some are met with as double salts of the colour base and zinc. In order to know if zinc became fixed upon the dyed fabric, a Malachite green, a Methylene blue, and a Violet, all containing zinc, were dyed separately upon cotton hose mordanted with tannate of tin, then rinsed, dried, soaped, and redried. In no case was any zinc found to be fixed upon the fabric.

hosiery "anilines" are in contact with the skin in forms as insoluble as the dyer can make them.

From several analyses of the ash from various hose dyed with "basic anilines," those given in table below are selected as typical.

These gave an average of 55·4 per cent. SnO_2 , and of 69·4 per cent. Fe_2O_3 , upon the three on which iron has been used as a "saddener."

4. *Dyeing Woollen and Mixed Wool and Cotton Hosiery*.—The dyeing of these two fabrics may be conveniently considered together, since the wool of both is dyed, whereas the cotton absorbs and retains traces of some colouring matters during the process of wool dyeing. The dyeing is divided into two classes:—I. Those colours which need the mordanting to be a separate operation from the dyeing. II. Those colours which admit of dyestuff and mordant being applied simultaneously.

In Class I, the use of bichromate of potash is all-important. The mordanting is attained by boiling the fabrics for about 1 hour in a solution of bichromate of potash, with addition of tartar, of sulphuric acid, of alum, or of other metallic salts. The fabrics are then well rinsed with cold water by machinery, put through hydro-extractor, and are then ready for dyeing. The dyeing is attained by boiling the hosiery with various dyewoods, chiefly logwood, old fustic, eudbear, madder, etc.

Before leaving the dyeing of cotton hosiery with "Aniline" colours, I would direct your attention to some of the facts brought before the Society of Dyers and Colourists (cf. *Journal* for November, 1884). (1) Mr. Ivan Levinstein says, "The German Government, after the most searching inquiries, permitted the use of all aniline dyes, with the exception of picric acid, for dyeing and colouring eatables and other purposes." (2) In the same *Journal* there are communications from twelve principal manufacturers of "anilines," and all agree that they have never heard complaints as to skin-irritating properties of "anilines" from the workmen whose hands and faces are continually covered with the dyes. (3) One gentleman, Mr. A. Nesbitt, states that he has "fed rabbits for many weeks on oats which had been steeped in strong solutions of magenta, violet, brown, orange, induline, chrysoidin, etc., without being able to find them any the worse for the treatment."

In these three references "anilines" in a soluble form are presented to the body, whilst in dyed

The variety of colours produced by this method is very great, ranging from black, dark blues, greens, browns, clarets to other lighter and brighter shades, all of which consist of an insoluble chromium lake, with rarely some trace of other metallic hydrates.

For our purpose to-night, Black—as represented by black cashmere stockings—is fairly typical of all these shades. It is the most heavily-chromed in mordanting, but otherwise is subjected to similar treatment as other shades. The use of bichromate of potash for mordanting wool and merino hosiery is very large, and in answer to a letter, asking when it first began to be used for *woollen hosiery*, Mr. Thomas Clark, of Loughborough, says: "I believe I began to use it about the year 1850." Since that time it has been increasingly used in mordanting woollen hosiery. The first table on next page gives five analyses of ash from black cashmere hose. These gave an average of 1·8088 per cent. Cr_2O_3 .

From the enormous quantities of wool and merino hosiery which have been dyed upon bichrome mordants during the past 35 years, it is difficult to

imagine any skin irritation charge being seriously made against goods so mordanted. It is well, however, to remember that the bichromate solution which penetrates and permeates the hosiery fabric becomes changed, possibly into insoluble chromic hydrate, during the dyeing operation, if not before; but in any case it is rendered insoluble.

Weight of Hose taken.	C ₂ O ₃ Found.	Remarks.
1. 41·225grms.	0·9346gm. = 2·267	The colours varied from the jet black to the rich blue black; also, sample 1 contained '051 Fe ₂ O ₃ ; sample 3 contained '083 Fe ₂ O ₃ .
2. 47·528grms.	0·8507gm. = 1·792	
3. 29·107grms.	0·4505gm. = 1·547	
4. 25·321grms.	0·4296gm. = 1·697	
5. 47·621grms.	0·8293gm. = 1·741	

In Class II., when the mordants and dyestuffs are applied simultaneously, we have animal, vegetable, and "azo" colours, and sulphonates of a colour base. Cochineal has, according to Mr. Thomas Clark, been used for dyeing scarlets, etc., upon woollen hosiery for "nearly sixty years." Tin mordants used for cochineal scarlets are very rarely employed for any other colour upon dyed hosiery. Indeed, for our purpose to-night, we may consider cochineal and tin mordants upon wool as things of a bye-gone era. The vegetable colouring matters are mainly old fustic, eudbear, madder, and "acid extract" of indigo and logwood.

The azo and sulphonated colouring matters most largely used are roccellin, Bordeaux R and G, orange 2, orange G, scarlets R and 3R, dark blues (*e.g.*, fast blues M.L.B.), whilst Naphthol Yellow S and Acid Magenta are also used to some extent. These colours all dye in an acid bath, usually along with alum, and are used for the production of scarlets, wine shades, dark greens, etc., as well as a variety of light bright tans and golds, drabs, slates, sages, etc. All these colouring matters, so far as they are used in hosiery dyeing, may be characterised as very inert, and not marked by any skin-irritating properties. MM. P. Cazeneuve and Lepine (*Compt. Rend.* 101, 1885) give results of very interesting experiments on men and animals by roccellin, which, in their opinion, is possessed of no toxic properties whatever; acid magenta is also non-poisonous; Naphthol Yellow S has not perceptible poisonous properties.

In all cases where dyestuff and mordant are applied simultaneously to hosiery, hydrate of alumina is deposited upon the wool and plays the part of a mordant. The following are analyses of ash from various woollen hose dyed in an acid bath, and which may be taken as typical of such colours:—

WEIGHT OF HOSE.	Colour.	Al ₂ O ₃ Found.	REMARKS.
33·589grms.	Wine colour	'0164gm. = '1382%	The navy blues are dyed with "extract" of indigo, and one of the various dark blues for wool. The scarlet and cardinal are dyed with "azo" scarlets, whilst the wine colours are dyed with "azo" reds, with slight admixture of "extract" of indigo.
80·901grms.	Navy blue	'1565gm. = '1935	
46·571grms.	Navy blue	'0573gm. = '1230	
76·312grms.	Scarlet	'1688gm. = '2213	
33·749grms.	Wine colour	'0326gm. = '0967	
32·561grms.	Cardinal	'0422gm. = '0129	

These give an average of 0·1309 per cent. Al₂O₃.

All colouring matters used in Class II. may fairly claim to have stood the test of time and wear, and all largely employed upon hosiery, but some, like extract

of indigo, have been very much longer employed than others.

5. "*Trimming.*"—When hosiery of whatever fibre has been dyed, washed, or even wet, it needs to be brought into shape and condition to be put upon the market. These ends are to a large extent obtained by "trimming." (1) The partly-dry hosiery which has been dyed with wrong side outwards is "turned," that is, the right side of the stockings, etc., are turned outwards by a boy inserting his arm in the stockings, etc. (2) These stockings, etc., are then pulled and dried upon a wooden board of the precise shape which it is desired to impart to them. (3) When dry the stockings, etc., are pulled off the board and straightened. These three operations are often conducted by two men and a boy, who are known as a "set." Two members of the "set" handle the stockings, etc., whilst damp and cold; the third handles them whilst hot and dry; and the hands of all three are coloured with the dye from the lot of goods at which they are at work. All hosiery is submitted to this process at least once, and frequently twice; after which it may be submitted to various other processes, all of which require each stocking, etc., to be handled separately.

After some inquiry I find there are about 250 to 300 people engaged in this work of trimming in and around Nottingham. These figures do not include those employed in and around Mansfield, Belper, Loughborough, Leicester, Hinckley. An average set of three will trim ten dozen pairs of stockings per hour; or taking one class of work with another, a set will trim 450 to 550 dozens per week on an average. It frequently happens that a "set" is at work upon goods mordanted with the same mordants and dyed with the same dyes for days together. But, on the other hand, these conditions may be changed several times a-day.

What, then, is the condition of the hands of these people employed in "trimming"? It is well to remember that in some respects our hands and feet are very similar. People have naturally moist or dry hands or feet. Dyed hosiery has to be handled, stocking by stocking, whilst damp and cold, as well as whilst hot and dry, by people the conditions of humidity of whose hands vary naturally. Owing to the friction applied by the hands to the dyed goods, the fingers and hands become covered with colour in pretty much the same way that the feet are coloured by wearing dyed cotton hosiery, etc. The friction causes a glazy appearance with a slight hardness of the skin when the man habitually has to strip the hot dry stockings off the board. But when the stockings are handled damp and cold, there is no sign of glaze and the hands are not hard.

If, then, dyes or mordants act as skin irritants, the

hands of these trimmers should be the first to show such irritation. Nothing, however, is further from the actual condition; such irritation is entirely unknown among trimmers. This conclusion is the

result of the observations and inquiries of myself and others extending over some years.

These considerations have an important bearing. The trimming of hosiery actually amounts to a very searching test of the skin-irritating properties of dyed hosiery *before it reaches the actual wearers*; or in other words, to a guarantee of the harmless character of the dye, etc.

6. *Wearing Hosiery.*—Probably the combined action of friction, heat, and moisture upon stockings or half-hose is greatest at the toe and the heel. To resist the greater wear and tear, all the better qualities are made stronger at toes and heels, and frequently over the whole foot sole, whilst wearers of dyed hosiery (specially cotton) will testify to their toes and heels being most coloured with the dye. From many observations I would say that *at the toe and heel* stockings are *acid* after a week's wear, whilst the intervening space on the hollow of the foot of the stockings do not indicate any appreciable change in their original slightly alkaline or neutral condition. This appears to indicate some action set up by increased friction between perspiration and the cotton fabric. It is of interest to state the fact now, although I hope at some future time to speak more fully about it when dealing with the solubility of the various metallic tannates and colour lakes in perspiration.

If it be granted, for the sake of argument, that the area of the sole of the foot represents the maximum area of a stocking which is subject to the severest friction and greatest combined action of friction with perspiration, then certain deductions will follow:—

We will take a plain (not "ribbed") stocking.

Now, an average woman's stocking presents an area in contact with the skin of 276 sq. ins. And a total *foot* area in contact with the skin of 59 sq. ins. Whilst the area of the sole of the foot which is in contact with the skin is..... 25 sq. ins.

(Double these figures are taken below in speaking of a pair of stockings.)

Thus, approximately, for no allowance is made for tightness or looseness of fit, and the fabric is elastic rather than rigid, the area of the sole of the foot is $\frac{1}{11}$ of the whole area of the stocking.

Taking 2½ lb. as an average weight for a dozen pairs of such stockings, a single pair will weigh 3oz. (= 1312½ grains), have a total area of 552 sq. in. in contact with the skin, and a total area over the soles of the feet of 50 sq. in. in contact with the skin.

Taking these figures, and turning to the analysis of ashes from various dyed hose, for the average percentage composition of the ash, we find—

Seal Brown Cotton.—Such a pair of stockings, with 552 sq. in. in area, weighing 1312½ grains, and with a percentage composition averaging CuO 1975 per cent., Cr_2O_3 1745 per cent., and Fe_2O_3 15400 per cent., would contain CuO 2592 grains, Cr_2O_3 2290 grains, Fe_2O_3 20212 grains, and therefore would only present $\frac{1}{11}$ of these quantities to the severest action of friction, heat, and perspiration; or 0.2356 grains CuO, 0.207 grains Cr_2O_3 , 1.837 grains Fe_2O_3 , which would be spread over 50 sq. in. in area.

*Wine Colours and Navy Blue Cotton.**—A similar pair with 552 sq. in. in area, weighing 1312½ grains, and with a percentage composition averaging SnO_2 554 per cent., Fe_2O_3 694 per cent., Al_2O_3 a trace, would contain SnO_2 7271 grains, Fe_2O_3 9108 grains, Al_2O_3 a trace, and therefore would only present $\frac{1}{11}$ of

these quantities to the severest action of friction, heat, and perspiration; or 0.661 grains SnO_2 , 0.828 grains Fe_2O_3 , a trace of Al_2O_3 , which would be spread over an area of 50 sq. in.

Black Cotton.—A similar pair with 552 sq. in. area, weighing 1312½ grains, and with a percentage composition averaging Fe_2O_3 1383 per cent., CuO 102 per cent., would contain Fe_2O_3 18151 grains, CuO 1338 grains, and therefore would only present $\frac{1}{11}$ of these quantities to the severest action of friction, heat, and perspiration; or 1.650 grains Fe_2O_3 , with perhaps 121 grain CuO, which would be spread over an area of 50 sq. in.

Turning from cotton to wool hosiery, and pursuing the same line of argument, it is well to remember that what applies to all-woollen hosiery applies also to mixed wool and cotton hosiery, but to a less degree—*e.g.*, all-wool stockings and a mixed wool and cotton one are dyed very frequently by one and the same method, the wool only being "dyed;" the cotton passing through the operation becomes "tinted" more or less permanently, but the cotton absorbs but very little of the mordant and dye which are upon the wool.

Again, taking the same figures for weight and areas of the stocking, and turning to the analyses of ash from wool hose for the average percentage composition, we find:—

Black Cashmere.—A pair with 552 square inches area, weighing 1312½ grs., and with percentage composition, averaging Cr_2O_3 18088 per cent. would contain Cr_2O_3 237405 grains; and, therefore, would only present $\frac{1}{11}$ of this quantity to the severest action of friction, heat and perspiration; or 21582 grains Cr_2O_3 spread over 50 square inches area. In thus selecting blacks we must remember that black represents the most heavily "chromed" colour; so that seal brown, dark clarets, myrtle green, some navy blue, and a host of lighter colours are comprehended, since the percentage of Cr_2O_3 includes the less.

Scarlets, Cardinals, Marones, some Navy Blues, Peacocks, and light and bright colours dyed with alum, etc., in an acid bath.—A pair with 552 square inch area, weighing 1312½ grains, and with a percentage composition averaging Al_2O_3 1309 per cent., would contain Al_2O_3 1718 grains; and, therefore, would present $\frac{1}{11}$ of this quantity to the severest action of friction, heat, and perspiration; or, 0.156 grains Al_2O_3 spread over 50 square inches area.

Very large deductions must be made from all these figures when we try to form any approximate idea of how much, if any at all, of the hydrated metallic oxides are absorbed by the skin. Washing in a hot alkaline liquid removes mechanically and chemically much of the hydrated oxides. When well worn out, the stockings still retain relatively large proportions of some of the hydrated metallic oxides.

It is very difficult to form any idea how long a pair of stockings is worn before being thrown aside, since it largely depends upon the activity and physique of the wearers as well as the quality of the colour. To see the best hosiery, both of manufacture and dye, well worn out with a marvellous amount of mending at the toes and heels, returned to the dyer with the naive question, "How is it the colour is gone?" is so common an experience, that it is highly probable the ordinary life of a good stocking frequently exceeds the tens of weeks in wear. In addition, I have more than once received from the wearers the information that "Their's never need mending the *first season*"; so that the actual time over which any skin absorption extends is great compared with the very small quantity of oxide present.

I must now conclude. I have endeavoured to put

* The methods of mordanting and dyeing justify bright reds, marones, clarets, navy blues, peacocks, and myrtle greens being all classed together here.

fairly before you several matters intimately connected with the dyeing and wearing of certain classes of hosiery. A brief consideration, say, of how long the wearing of dyed hosiery has been in vogue, of the large quantities annually produced, of the harmless character of the colouring matters employed, of the small quantities of metallic oxides or salts present in the colour lake, of the comparatively large area over which the colour lake is spread, of the amount of metallic oxide still remaining upon a well worn-out stocking, together with the "trimming" which hosiery undergo before being worn, will collectively furnish very strong evidence of the harmless character of fibres mordanted with iron, tin, aluminium, or chromium mordants, and dyed with the colouring matters usually employed in hosiery dyeing.

It remains for me to express my hearty thanks to my friend, Mr. H. Doidge, for much valuable assistance in the laboratory.

An Addendum to this paper, by Mr. H. Forth, together with the Discussion on both papers, will appear in the next number of the Journal.

A paper "On some Points in the Analysis of Oils, with Special Reference to Olive and Rape Oils," by L. Archbutt, notice of which arrived too late for insertion in the last number, and which was read on 9th April, will also shortly appear.

DENNIS B. HARRISON IN THE CHAIR.

A PAPER was read by W. RAMSAY, Ph.D., on the Nickel and Cobalt Ores of New Caledonia, and after a short discussion Dr. Ramsay read the following paper :—

ON THE PRODUCTS OF DECOMPOSITION OF CHLOROFORM AT A RED HEAT.

BY W. RAMSAY, MILD., AND SYDNEY YOUNG, D.S.C.

IN an investigation on dissociation in which we have been engaged, it has been our aim to discover bodies which dissociate within convenient limits of tem-

perature. Our attention was drawn to the existence of a substance named carbon monochloride, by Julin, by a perusal of Professor Carnelley's recent paper on the Periodic Law, *Phil. Mag.* 20, 506. It is there pointed out that the molecular weight of this substance must be much higher than that corresponding with the formula C_2Cl_2 ; and Berthelot (Watts' Dictionary, vol. i. 768) suggested the formula, $C_{10}Cl_{10}$ as probable, without having determined the vapour density of the body. In the *Journal of the Chemical Society*, 1867, p. 443, Mr. Henry Bassett investigated the subject, and professed to have established the identity of Julin's chloride of carbon with hexachlorobenzene, then recently discovered by Dr. Hugo Müller; the body obtained by him by passing chloroform vapour through a red-hot tube filled with broken porcelain gave numbers on analysis corresponding to the empirical formula, C_2Cl_2 , and he also determined its vapour density presumably by Dumas's method; finding 10.06 instead of 9.87, the theoretical vapour-density of $C_{10}Cl_{10}$ compared with air. There can be no doubt, therefore, that Mr. Bassett had obtained hexachlorobenzene. But the properties of the substance described in Watts' Dictionary, vol. i. p. 768, under the heading "Protochloride of Carbon," do not agree with those of hexachlorobenzene, inasmuch as the body is stated to melt, boil, and sublime between 175° and 200° ; whereas hexachlorobenzene melts at 231° , and boils above 300° . Both compounds, however, are described as crystallising in needles. The substance described in Watts' Dictionary is said to be very soluble in alcohol, while hexachlorobenzene is sparingly soluble. It is evident that these discrepancies are not explained by Bassett's results. The vapour of chloroform was passed through a combustion-tube, filled with asbestos, heated to dull redness by a long-flame burner. The product was distilled and the portion boiling below 85° was again passed through the tube; and this process was repeated until a sufficient quantity had been collected. The product was allowed to evaporate until crystals were deposited. These were separated by squeezing through cloth, dried, and sublimed by heating with aniline-vapour. On cooling the mother-liquor a fresh crop of crystals was obtained, which were treated in the same way. It soon became apparent that the solid consisted of two substances, one more volatile than the other; the more volatile was easily soluble in alcohol, the less volatile with difficulty. The less volatile substance was volatilised over a flame, and was deposited in needles. We found that crystallisation from acetone formed the best means of separation. On cooling a hot solution of both substances, containing a large proportion of the more volatile substance, plates of the latter were deposited in a nearly pure state; but after standing for some time long flexible needles of a pink colour made their appearance. It was necessary, therefore, to separate the plates soon after they were deposited. A second crystallisation from acetone gave the more volatile substance in a state of purity. The needles are almost insoluble in cold acetone, but being more soluble when hot their purification presented no difficulty.

These bodies proved to be hexachlorethane and hexachlorobenzene respectively, as shown by the following results :—

	C_2Cl_4 .	C_2Cl_4 .	C_2Cl_6 .	C_4Cl_6 .	C_6Cl_6 .	A.	B.	C.	D.
Cl, per cent	92.19	85.50	89.84	81.55	71.67	89.74	71.29	83.40	87.27

perature. Our attention was drawn to the existence of a substance named carbon monochloride, by Julin, by a perusal of Professor Carnelley's recent paper on the Periodic Law, *Phil. Mag.* 20, 506. It is there

A. PLATES—

Analysis : 0.1765 grm. gave 0.6411 grm. AgCl, equal to 89.74 per cent. of chlorine. Calculated for C_2Cl_6 , 89.84 per cent.

The behaviour of the substance on heating was compared with that of a specimen of hexachlorethane, and was found to be identical.

B. NEEDLES—

Analysis: 0.2319grm. gave 0.6973grm. AgCl, equal to 74.29 per cent. of chlorine. Calculated for C_2Cl_4 , 74.67 per cent.

B. VAPOUR-DENSITY.—By Victor Meyer's method in vapour of boiling sulphur:—

Temperature of air, 12.5°.

Pressure, reduced to 0°, and corrected for vapour pressure of water, 75mmms.

Volume, 9.25ccs.

Weight of substance, 0.1088grm.

Vapour-density, 139.0 ($H=1$).

Calculated, 142.2.

The mother-liquor out of which these substances had deposited, and which amounted to only a few ccs., was fractionated as far as was possible. A portion boiling between 117.6° and 120.6° proved to be for the most part tetrachlorethylene, C_2Cl_4 .

C. ANALYSIS:—

i. 0.1805grm. gave 0.6065grm. of AgCl, equal to 83.01 per cent. chlorine.

ii. 0.1562grm. gave 0.5298grm. of AgCl, equal to 83.80 per cent. chlorine.

Calculated for C_2Cl_4 , 85.50 per cent. chlorine.

Vapour-density, by V. Meyer's method, at the temperature of boiling aniline ($t=184^\circ$).

i. Temperature of air, 11.3°.

Pressure reduced to 0°: and corrected for vapour-pressure of water, 729.5mmms.

Volume 11.0ccs.

Weight of substance, 0.0792grm.

Vapour-density, 87.21.

ii. Jacketed with bromonaphthalene vapour ($t=280^\circ$).

Temperature of air, 11.65°.

Pressure, corrected, 741mmms.

Volume 10.0ccs.

Weight of substance, 0.0718.

Vapour-density, 85.72.

Vapour-density calculated for C_2Cl_4 , 82.8.

Between the temperatures 175° and 200° the product was chiefly hexachlorethane, but below 175° a small quantity of some other body distilled, too small however to isolate.

D. A fair amount boiled between 210° and 220°, and although it was evidently impure, it was analysed, and its vapour-density was determined.

ANALYSIS:—

i. 0.1563grm. gave 0.5516grm. AgCl, equal to 87.19 per cent. of chlorine.

ii. 0.1202grm. gave 0.4250grm. AgCl, equal to 87.35 per cent. of chlorine.

Vapour-density, by V. Meyer's method, in vapour of bromonaphthalene (280°).

i. Temperature of air, 13.8°.

Pressure, reduced to 0°, and corrected for vapour-pressure of water, 739mmms.

Volume 7.75ccs.

Weight of substance, 0.0795grm.

Vapour-density ($H=1$), 120.9.

ii. Temperature of air, 16.2°.

Pressure, reduced and corrected, 746mmms.

Volume 9.1ccs.

Weight of substance, 0.0397grm.

Vapour-density, 118.8.

This body is evidently a mixture. The annexed table gives a summary of the percentage of chlorine contained in the known chlorides of carbon, and their vapour-densities; and it is evident that A is hexachlorethane; B, hexachlorobenzene; C, tetrachlorethylene; and D, a mixture possibly containing hexachlorethane.

Note.—From a subsequent conversation with Mr. Bassett, it appears that the temperature to which he heated the chloroform vapour was much higher than that to which we subjected it, thus accounting for the much larger yield of hexachlorobenzene which he obtained.

Journal and Patent* Literature.

I.—GENERAL PLANT, APPARATUS, AND MACHINERY.

Improvements in Filter-presses. R. J. Friswell and A. Myall, London. Eng. Pat. 3055, March 9, 1885. 8d.

THE patentees state that in filter-presses of ordinary construction, in which the filtering chambers are formed by recessed plates having corrugated drainage surfaces, the operation is retarded by reason of the cloths being forced into the grooves, and the flow of liquid in them thereby stopped. This they state can be obviated by covering the grooved surfaces with woven wire-work, or an incompressible woven material secured round the central orifice by a thin metallic ferrule and sprung into a groove or recess in the periphery of the chambers. The cloths are placed over this in the ordinary manner. Seven claims cover this and the mode of carrying it into effect.—C. C. H.

An Improvement in Fusible Plugs. William Henry Bailey, Salford. Eng. Pat. 3637, March 21, 1885. 6d.

A SHORT length of open tube is screwed into the boiler plate, and on to the end projecting into the water space is fastened, by means of a screw cap, a fusible metal plate covered with a second disc of copper or brass, which will be forced out by the pressure of steam when the fusible plate melts; the water thus never comes into contact with the fusible metal, and chemical action is therefore avoided.—W. G. M.

Improvements in the Method of and Apparatus for Purifying the Feed-water for Steam Boilers. H. E. Newton, London. From A. L. G. Dehne, Halle-on-Saal. Eng. Pat. 5149, April 25, 1885. 8d.

THE feed-water is first passed through a heater, next into a closed vessel, in which it is mixed with one or more reagents, depending upon the impurities to be removed. From this vessel it passes into a filter-press, from the closed continuous outlet channel of which it is drawn by a pump; the delivery pipe from the pump passes it into a third vessel, where it comes in contact with iron turnings or coke for the purpose of removing "any earthy matters that may still be retained;" from thence it passes into the boiler. The reagents are pumped into the closed vessel by a small pump which bears a fixed proportion to the pump dealing with the whole of the water; both being driven simultaneously, the proper proportion of reagent is always delivered, notwithstanding any variation in the speed of pumping.—C. C. H.

Method of and Apparatus for Treating Semi-liquid Substances with Purifying or other Liquids. E. Langen, Cologne. Eng. Pat. 4473, April 10, 1885. 8d.

THE apparatus consists of a perforated hollow cylinder A, revolving on bearings, and running in a trough B, between scrapers C. The pump D communicates with the trough B by means of its suction pipe, and its

* Any of these specifications may be obtained by post, by remitting the cost price, plus postage, to Mr. H. Reader Luck, Comptroller of the Patent Office, Southampton Buildings, Chancery Lane, London, W.C. The amount of postage may be calculated as follows:—

If the price does not exceed 8d.....	4d.
Above 8d., and not exceeding 1s. 6d....	1d.
" 1s. 6d., " " " 2s. 4d....	1d.
" 2s. 4d., " " " 3s. 4d....	2d.

delivery pipe communicates with supply trough F. When a semi-fluid crystalline mass, such as sugar, suspended in a liquid is passed over the cylinders, the liquid used for washing in the end cylinder of the series is withdrawn by the pump D, and supplied to the next cylinder from the trough F; from the second

which large volumes of dust-laden air are passing, the impurities being left behind. Vertical cloth bags are secured with their lower open ends to the tops of boxes which receive the dust-laden air in front of an inclined internal partition, behind which the deposited dust is collected, and is removed by the action of a screw ear-

FIG. 1.

FIG. 2.

cylinder it is again withdrawn by another pump and passed on to another cylinder, and so on through the series. The patentee claims this method of washing or treating substances, and also the combination of apparatus described and shown.—C. C. H.

Improvements in Metallic Thermometers with Dials. W. H. Gauntlett, Middlesbrough-on-Tees. Eng. Pat. 5671, May 8, 1885. *Sd.*

THE inventor makes use of the difference of expansion of two strips of dissimilar metals soldered together and bent in the shape of an open ring, giving motion in opposite directions to the ends of the ring, which carry between them the spindle of the indicator-hand. The ends are fashioned to overlap each other in the plane of the ring, and in a manner parallel to their own motion. The spindle being held between them and touching them both, is caused to turn round by their opposite motions, without at the same time in any way changing the position of its axis, which remains steady as if held in bearings. The latter are therefore dispensed with. The parallel end bars of the ring are by preference provided with fine teeth, the spindle being cut to match, so that the movement of the latter is a positive one.—B.

Improvements in Apparatus for Separating Dust from Air. H. H. Lake. From Ch. H. Morgan, Buffalo. Eng. Pat. 15,779, December 22, 1885. *Sd.*

THIS invention relates to apparatus for separating and collecting the dust deposited on filter-bags through

rier. The upper closed ends of the filtering bags are suspended from pulleys and shafts, which cause their periodical alternate rise and fall, simultaneously with a slight shaking, the result being a loosening and dropping of the deposited dust. At the time of the dust falling, the supply of air through the filters is arrested through the self-acting closing of the inlet valves provided in the partition, whilst other valves open to admit the dust to the creepers, the action of the valves being reversed, when the bags are in position again for the next charge of air.—B.

Distilling Apparatus. H. J. Haddan, Strand. From A. Liedbeck, Stockholm. Eng. Pat. 5654, May 7, 1885. *Sd.*

IN this invention a distilling vessel is used of cylindrical shape with vertical axis. To the centre underneath the vessel is fixed a hollow shaft, to which suitable quick rotary motion can be given. Up the centre of the shaft

passes a hollow tube, through which the liquid to be distilled is conveyed to the vessel, whilst the vapours of distillation pass down through the annular space left

between the shaft and the tube, and are carried away by a radial pipe connected to the lower part of the shaft by means of a conical metallic revolving joint. The vessel may be exposed to heat in any convenient manner, and distillation may be carried on in vacuo or under air pressure, whilst the axis of the apparatus may be inclined instead of vertical. The accompanying figure shows a section of the apparatus, and indicates the principle of construction.—B.

Improvements in Apparatus for Measuring Equal Quantities of Fluids. J. H. Wüster, Ybbs, Austria. Eng. Pat. 72, January 2, 1886. 8d.

THIS is a contrivance for delivering equal volumes of fluids out of a containing vessel upon successive openings

FIG. 1.

and closings of a tap. The plug of the tap is hollow, and of sufficient capacity for holding the largest quantity of the liquid that may be required to be measured out. It

FIG. 2.

has two openings, communicating respectively with the supply and discharge pipes, but placed so that communication cannot take place with both pipes simul-

taneously. A float within the tap regulates and measures the liquid admitted when the interior is in connection with the supply, and on the tap being partly turned round, the liquid is discharged. The measuring receptacle may be a separate vessel with a two-way tap fitted underneath, and the latter may be made either to turn or to slide. The two figures show the latter arrangements, the first with a turning tap underneath, the second with the sliding tap. In both, B is the supply pipe, J the discharge, and D the measuring vessel.—B.

Improved Method for the Manufacture of Anhydrous Ammonia and for the Utilisation thereof for the Production of Cold or Work or of both Cold and Work together. A. Osenbrück, Bremen. Eng. Pat. 719, January 16, 1886. 8d.

GLYCERINE is proposed as a substitute for water for absorbing ammonia in ammonia gas-engines. The boiling temperature of glycerine being much higher than that of water, the separation of ammonia from a glycerine solution can be effected at a temperature where even an aqueous glycerine solution gives off a perfectly anhydrous ammonia, which after being condensed, on evaporating will considerably increase the useful effect of the engine. The use of ammonia as a motive power can be effected in two different ways. Firstly by driving off the ammonia from the glycerine solution, and then condensing the same, such liquid being then evaporated for the purpose of producing cold. It is then caused to act in the cylinder of a motor engine so as to produce an amount of work corresponding to its pressure and quantity, and lastly it is again absorbed. Or the elastic pressure of the ammonia vapour separated from the glycerine solution in the distilling apparatus is directly applied in the cylinder of a motor engine for the production of work, after which the vapour is again absorbed. The author describes the details of an apparatus based on the latter mode of operating.—S. H.

II.—FUEL, GAS, AND LIGHT.

Improvements in Distilling and Obtaining Useful Products from Coal or other Carbonaceous Mineral, and in Apparatus therefor. F. J. Rowan, Glasgow. Eng. Pat. 2693, February 28, 1885. 11d.

IT is proposed to combine in one continuously-working arrangement of apparatus, a distilling chamber or retort, and a chamber for converting the coke or fixed carbon with the aid of steam, but without the introduction of air. Both portions of the apparatus are heated externally, a high temperature being applied for the final conversion of the coke, in order to minimise, and, if possible, prevent the formation of carbonic anhydride in the water-gas resulting from the decomposition of the steam introduced. The coal passes continuously, first into and through the distilling chamber, and subsequently into the second, or coke-converting chamber, without being withdrawn from the apparatus or cooled. The ash which collects at the exit end of the second chamber may be removed either periodically or continuously by any suitable appliance. This apparatus may be adapted with advantage to gas-works retorts. A special feature is said to consist in the reduced volume and increased richness of the gas, due to the absence of nitrogen, which greatly facilitates its treatment by condensers and scrubbers for the purpose of separating condensable hydrocarbons and ammonia.—D. B.

Improvements in or incidental to the Separation of Ammoniacal Products and Tar from Producer or other Furnace Gases. L. Mond, Chester. Eng. Pat. 8973, July 25, 1885. 6d.

THE condensation of tar and ammoniacal products from producer or furnace gases is usually effected by passing the gases through iron pipes exposed to the air or cooled by water. This operation being very tedious and in-

volving the exposure of large surfaces, the following method has been devised. The gases are passed through a scrubber, in which they are cooled to 40° by a current of water flowing in a direction opposite to the current of gas. The water issuing from this scrubber, and containing ammonia and tarry products, is cooled, an apparatus being employed in which the hot water flows in one direction and the cold water in the opposite direction. The water, after being cooled in this manner, is again passed through the scrubber, and then through the cooling apparatus, and so on, the same water being constantly used. The steam in the producer gases being condensed by this treatment, a quantity of water equivalent to the condensed steam is drawn off at intervals, and from it the ammonia is recovered. To obtain the latter in the form of sulphate direct, the gases issuing from the producer are passed into scrubbers, through which a very dilute solution of sulphuric acid (2 of acid to 100 of water) flows. The solution of ammonium sulphate thus obtained is used repeatedly, sulphuric acid being added after each absorption, in order to bring the solution to the original acidity. This operation is continued until a concentrated solution is obtained, from which the salt is separated by crystallisation and evaporation. The tar which accumulates in the water used in the scrubbers is separated and removed from time to time, whilst the gases, after leaving the cooler, are burned. A saving of all, or the greater part of the fuel now used for raising steam for the purpose of working gas producers, under patents Nos. 3821 and 3923 of 1883, is said to be effected by this method. See also this Journal, 1883, 233 and 236.—D. B.

An Improved Process of Extracting from Carboniferous Materials the Products met with in the Process of converting into Gases, and of withdrawing Gases. H. Stier, Zwickau, Saxony. Eng. Pat. 12,298, October 15, 1885. 8d.

This process is based on the fact that the distilled products from carbonaceous materials of little value contain a somewhat larger quantity of carbon than is necessary for their conversion into gas. It depends also on an arrangement, by means of which, in utilising the preceding fact, the processes of gasification and distillation assist one another. The inventor claims: "A method for obtaining the products of abstraction of gas (distillation), of gasification (heating gas), or for obtaining distilled products, according to which method, alternately in one chamber of each pair of the chambers, the gasification takes place, and in the other chamber the abstraction of gas (distillation) in such a manner that the last operation is always effected by the first operation."—D. B.

Improvements in the Manufacture of Briquettes or Fuel Blocks. W. Black, Stanrigg, Airdrie. Eng. Pat. 3790, December 22, 1885. 6d.

PULVERISED coal dross, peat, or similar carbonaceous material is compressed into blocks with shale-oil pitch. When the blocks are to be used in lieu of gas-coal for the production of illuminating gas, the hydrocarbon products left in the distillation of mineral oils may advantageously be substituted for the shale-oil pitch.

—A. R. D.

An Improved Process of Treating Coal Dross and other Carbonaceous Substances. W. Black, Stanrigg, Airdrie. Eng. Pat. 4414, January 5, 1886. 4d.

THE carbonaceous matter is heated in a closed vessel under reduced pressure, whereby it is freed from moisture and any air or gas that it may contain. While still under reduced pressure, it is impregnated with pitch or oil, such as the residual products of the distillation of mineral oils. The resulting mass may be used in its amorphous condition, or formed into briquettes by suitable machinery. It is available for fuel or for the production of illuminating gas.—A. R. D.

Improvements in Apparatus for Enriching Illuminating Gas. Jas. Parkes, Aston, Warwickshire. Eng. Pat. 454, January 11, 1886. 6d.

THE carburetter is a vessel placed so as to receive heat from one of the burners, and has an inlet pipe (cast in one piece with it) so disposed as to cause the entering gas to impinge upon the surface of the heated hydrocarbon in the vessel. The outlet pipe passes down obliquely through the interior of the carburetter, the heat of which prevents its clogging up.—A. R. D.

Apparatus for Combustion of Liquid Hydrocarbons. Percy Tarbutt, London. Eng. Pat. 5599, February 4, 1886. 8d.

WITHIN the firebox of the furnace or boiler to which this invention is applied, a combustion chamber of refractory material is placed, with openings for the issue of the flame and products of combustion. Into this combustion chamber liquid hydrocarbons are injected by means of a jet of steam which has been superheated by passing through a coil of pipe situated in the lower part of the combustion chamber. The air required is admitted round about the injector. Water enters the superheating coil from a pressure tank supplied by a pump.—A. R. D.

III.—DESTRUCTIVE DISTILLATION. TAR PRODUCTS, Etc.

The Transformation of Pyrroline into Pyridine. M. Dennstedt and J. Zimmermann. Ber. 18, 3316—3318.

SOME time ago it was shown that by the action of chloroform and bromoform on potassium pyrroline, chloro- and bromopyridine respectively are formed. The latter is reduced, bromine being eliminated and pyridine and hydropyridine formed. The presence of pyridine in the reduced compound was shown by Ciamicián and Silber, who also found that chlor- and bromoform act similarly upon pyrroline in presence of potassium and sodium alcoholate. With methylene chloride, on the other hand, no reaction occurs. When methylene iodide, pyrroline, and sodium methylate are heated in sealed tubes to 200°, pyridine is formed, which fact was confirmed by the analysis of the platinum salt. The yield was, however, exceedingly small, so small that the reaction cannot throw any fresh light upon the formulae of Baeyer and Schiff.—J. B. C.

α - and γ -Picolines. O. Lange. Ber. 18, 3436—3441.

THE author has separated α -picoline from animal oil by means of its sparingly-soluble mercuriochloride, having found that the process adopted by Weidel, and involving fractional crystallisation of the α - and γ -picoline platinochlorides, is less practical. The mercuriochloride of α -picoline is obtained in a microcrystalline and almost pure form from the fractions boiling at 128—130°, 130—133°, and 133—136°. It is sparingly soluble in cold, readily soluble in hot water, and melts at 154—155°. The pure base, obtained by decomposing the mercuriochloride with caustic potash and distilling with steam, was found to boil at 129—130° (and not 133·9° as given by Weidel, Ber. 14, 2008). Its specific gravity at 0°, compared with water at 4°, is 0·96559 (Weidel, 0·96161). The platinochloride forms small crystals melting at 178°; the aurochloride and the picrate crystallise in needles, melting at 167—168° and 165° respectively. Both these last-named salts are readily soluble in water. γ -picoline is most conveniently prepared by employing Ladenburg's synthetic method with pyridine and methyl iodide. On distilling the product obtained from pyridinemethiodide, two principal fractions are yielded, which boil at 127—134° and 145—150° respectively. The former contains α -picoline, whilst the latter consists mainly of γ -picoline. This base, when pure, boils at 144—145°, and has a specific gravity of 0·9708 at 0°, compared with water at 4°. On oxidation, isonicotinic acid is obtained—a

reaction which proves that the methyl group of this picoline is in the γ -position to the nitrogen. The salts of the base are more or less sparingly soluble in water. The platinumchloride melts at 225° – 226° , the anrochloride forms fine laminae melting at 205° , the mercuriochloride long white needles melting at 136° – 138° , and the picrate silky needles melting at 156° – 157° .—D. B.

Note on Metacresol. W. Staedel. Ber. 18, 3443–3444.

METACRESOL is generally described as a liquid which does not solidify even at -80° . The author, however, shows that when prepared in a pure form from metatoluidine obtained from metanitrobenzaldehyde, according to Widmann's method, it can be made to crystallise when cooled in a freezing mixture of ice and salt to -18° by the addition of minute crystals of phenol, which it resembles in crystalline form. Metacresol solidified in this manner, melts at 3° – 4° . Similar trials were made with commercial metacresol, but the results were less satisfactory. In a freezing mixture composed of ether and solid carbonic anhydride, a glass-like mass was obtained. The author is continuing his experiments in this direction.—D. B.

On 1:3:4 Metaxyleneol. O. Jacobsen. Ber. 18, 3463–3464.

IN a recent paper by Staedel and Hölz (Ber. 18, 2919), 1:3:4 metaxyleneol has been described as a solid crystalline substance, melting at 27° – 28° . The author, on investigation, found that although this xylenol can be obtained in a crystalline form, its melting-point is lower than that given by Staedel and Holz. He obtained numbers varying between 25° – 4° and 26° . The true boiling point is 211° – 5° , Staedel's number 216° – 5° being due to an error in his thermometer.—D. B.

Improvements in obtaining Ammonia in connection with the Distillation of Oil-yielding and Carbonaceous Minerals. A. Neilson and J. Snodgrass, Inkermann, N.B. Eng. Pat. 4902, April 21, 1885. Sd.

THIS invention, which is applicable to horizontal as well as to vertical or inclined retorts, is carried out in the following manner:—Each retort is worked with separate complete charges, and after having worked off the whole or larger quantity of the oil in the ordinary way, air and steam, previously mixed, are introduced into the retort, all external heating being discontinued. The introduction of air in this way causes the combustion of the carbonaceous matter remaining in the retort, and the production of increased heat, the result of the action being the evolution of a large amount of ammonia in addition to that obtained in the primary distillation. —D. B.

IV.—COLOURING MATTERS AND DYES.

Experiments in the Preparation of Aniline Black. Chem. Zeit. 9, 1671.

FOUR experiments were made with the following quantities, in which aniline hydrochloride was decomposed with KClO_3 and HCl , and a small quantity of CuCl_2 then added:—

CuCl_2 .	Aniline hydrochl.	Chlorate.	HCl (15 per cent.)
2	1grm.	5grm.	5cc. bad yield.
2	1 "	10 "	10 " good "
2	1 "	20 "	20 " super oxidised.
2	1 "	30 "	30 " "

By oxidation in neutral solution a bad yield was obtained. In experiment 2, from 1grm. aniline salt, 51grm. aniline black was obtained—that is, 70 per cent. of the aniline used. On a larger scale 100grms. aniline salt were dissolved in 250grms. water, 5grms. CuCl_2 added, to this 100cc. strong hydrochloric, and then a hot solution of 100grms. KClO_3 . The action occurred with almost explosive violence, and with evolution of chlorine, the mass becoming solid. The yield of aniline black was

90grms. Of this aniline black, 20grms. were heated with 40grms. aniline for $\frac{1}{2}$ hours to 180° , the excess of aniline being then removed with hydrochloric acid. A black substance remained behind, soluble in alcohol, possessing, on drying, a metallic lustre. The above method for the preparation of aniline black is similar to that of Suida and Liechti, whose experiments were commenced at a later period. The opinion of these chemists—viz., that aniline black is formed essentially from aniline chlorate—is in accordance with the result of the authors' second experiment. In order to transform aniline salt into aniline chlorate, equal molecules of both compounds are necessary, and these correspond to equal parts by weight.—J. B. C.

A By-product in Commercial Phenyl-hydrazine. E. von Meyer. J. Prakt. Chem. 1885, 32, 430.

PEITZINGER has observed that upon mixing phenylhydrazine with benzene, a crystalline body separates on shaking. The substance contains sulphur, and forms small saponaceous foliated crystals, insoluble in water and benzene, and melting at 96° . The compound is very unstable, decomposes in the air, and cannot be purified by recrystallisation. Its solution in acetone leaves, on evaporation, a dark oil smelling strongly of phenylmercaptan. The substance dissolves in caustic soda, with a reddish colour. HCl precipitates from this solution a dull green compound. On heating with HCl in a closed tube to 230° , sulphur is split off as CS_2 . —J. B. C.

Para-methylisatoic Acid and other Derivatives of Para-methylisatin. W. Zanaotovic. J. Prakt. Chem. 33, 57–75.

THE object of the author is to show the relationship of p -methylisatin to isatin by a comparison of their chemical behaviour. This has been fully demonstrated by the following experiments. The p -methylisatin, which served as a basis for this investigation, was prepared from p -tolyl- p -methyloxysatin by the action of dichloroacetic acid upon p -toluidine. Like isatin, p -methylisatin is oxidised by chromic acid in glacial acetic solution to p -methylisatoic, or anthranilcarboxylic acid—

This acid differs from isatoic acid in being very much more stable in presence of dilute mineral acids. Strong nitric acid forms a nitro-compound. With strong HCl it gives the hydrochloride of methylantranilic acid—

from which the free acid is readily obtained as a crystalline mass, identical with Jacobsen's α -amido- m -tolnic acid—

With nitrous acid it is converted into the corresponding oxyacid or p -methylsalicylic acid. By the action of aqueous ammonia upon p -methylisatoic acid, p -methyl-anthranilamide is formed with evolution of CO_2 .

aniline acts similarly, and also phenylhydrazine, the latter forming the compound—

Methyl alcohol heated with p -methylisatoic acid to 180° gives p -methylantranilic-methyl-ether. Attempts to oxidise the methyl group of the acid gave unsatisfactory results. p -Methylisatin gives, with acetic anhydride, an acetic derivative, in which the acetyl group, as in isatin, is attached to the N atom. This compound gives amides with NH_3 . p -Methylisatin forms with phenylhydrazine, a compound having the formula—

—J. B. C.

Liebermann's Phenol Colouring Matter. T. Lehmann and J. Petri. Arch. Pharm. (3), 23, 243—248.

NITROSYL-SULPHONIC ACID gives, with phenol, two substances, one of which is Liebermann's colouring matter, and has already been the subject of investigation. This colouring matter gives a characteristic nitro-compound, with fuming HNO_3 , forming a dark green powder, soluble in alcohol and ether, with a green colour similar to chlorophyll, which it also resembles by its peculiar fluorescence. If the colouring matter, whilst still moist, from H_2SO_4 used in its preparation, be heated to 100° , it undergoes a change as shown by the spectroscopic, and then possesses a colour similar to that of litmus, and may be employed as a substitute for the latter in volumetric analysis. The preparation of this compound resembles that of the previous one; 5cc. phenol are mixed with 5cc. conc. H_2SO_4 , the mixture being cooled. To this 20cc. nitrosyl-sulphonic acid are added drop by drop. The solution is then heated to and kept at 80° until the melt has become dark violet, and a sample mixed with H_2SO_4 until transparent, does not give the characteristic spectrum for Liebermann's colour. The mixture is then poured into cold water, whereupon the new substance separates out as a dark violet amorphous powder. After washing and drying at 100° , it may be dissolved in ether, and used as an indicator.—J. B. C.

Azonaphthalene and its Derivatives. R. Nietzki and O. Goll. Ber. 18, 3252—3260.

THE authors previously prepared a compound, to which they gave the name of α -azonaphthalene (this Journal, 1885, 276). They now endeavour to determine its constitution. The preparation of the compound has been simplified. 1 part amidoazonaphthalene is dissolved in 100 parts of 95 per cent. alcohol, 5 parts concentrated H_2SO_4 added, and NaNO_2 dissolved in the least quantity of water poured into the warm liquid. The violet colour of the liquid changes to a red-dish yellow. The liquid is boiled for some hours, and the product precipitated with water. This crude product is subsequently dissolved in hot aniline, and alcohol added to the solution, when blue crystals of azonaphthalene separate after cooling. The constitution of azonaphthalene may be determined with a comparative degree of certainty from its formation. α -Naphthylamine condenses with diazo-compounds, and the azo-group takes up the second α -position to the amido-group of the same benzene nucleus. Amidoazonaphthalene splits upon reduction into α -naphthylamine and α — α naphthylene diamine, the latter giving naphthoquinone. The formula will, therefore, be $\text{C}_{10}\text{H}_7\text{N}=\text{N}\cdot\text{C}_{10}\text{H}_7(\text{N}:\text{N}=\alpha:\alpha)$. The compound behaves like the azo-compounds of the benzene series. With reducing agents it gives hydrazo-naphthalene, from which two isomeric diamidodiphenyls are formed. With alcoholic ammonium sulphide the azo- and hydrazo-compounds give α -naphthylamine. With zinc dust in alcoholic soda solution, azonaphthalene gives hydrazonaphthalene, a colourless substance crystallising in scales which melt at 275° . It is insoluble in water, soluble in alcohol, ether and benzene. As in the case of hydrazobenzene, hydrazonaphthalene, when treated with mineral acids, gives two isomeric diamidodiphenyls. If hydrazonaphthalene be heated with dilute HCl , it dissolves, and on addition of conc. HCl , "Naphthidine" hydrochloride separates out. Alkalis liberate the free base, which crystallises like benzidine in scales melting at 198° , and has the formula—

It forms crystalline salts with two equivalents of acid, and a diacetyl-derivative with acetic anhydride. Oxidising agents like Fe_2Cl_6 , CrO_3 , or Cl give, with solutions of naphthidine salts, a beautiful carmine coloration. With nitrous acid it yields a diazo-compound which combines with the sulphonic acids of β -naphthol with the formation of violet azo-colouring matters. The phenol could not be obtained pure; but by the action of alcohol the hydrocarbon dinaphthyl was obtained, identical with Lossen's α - α -dinaphthyl. The second and soluble hydrochloride

obtained by the action of HCl on hydrazonaphthalene, has, from its similarity to diphenylamine, been named "dinaphthylamine." It has the peculiar property of being decomposed by boiling with acids (even with acetic and picric acids), into ammonia and dinaphthylimide. When oxidised, it yielded phthalic acid, but no naphthoquinone. Its diazo-derivative yields the same dinaphthyl as dinaphthidine. The difference between these two bodies must, therefore, be due to different positions of the amido group, which the author discusses in detail.

The above-mentioned dinaphthylimide is formed if dinaphthylamine be heated with strong HCl to boiling, and separates out as an insoluble colourless crystalline substance. The filtrate contains NH_4Cl . This compound has the formula $\text{C}_{20}\text{H}_{13}\text{N}$, and is formed according to the equation:— $\text{C}_{20}\text{H}_{16}\text{N}_2=\text{C}_{20}\text{H}_{13}\text{N}+\text{NH}_3$. The stability of the one N atom makes it appear that the substance is dinaphthylcarbazon—

and the various reactions given confirm this view. It crystallises in colourless needles or scales melting at 216° , and soluble in alcohol, benzene and glacial acetic acid. It yields nitroso- and acetyl-derivatives.—J. B. C.

Action of Acetone upon Aniline. C. Engler and P. Riehm. Ber. 18, 3296—3297.

A REPLY to C. Beyer, who found that by the action of aniline on acetone, no α - γ -dimethylquinoline is formed. The authors have repeated their experiments with the former results (this Journal, 1885, 740).—J. B. C.

By-products of Quinaldine. O. Doebner and W. v. Miller. Ber. 18, 3352—3353.

EINHORN having recently described an aldehyde of the quinoline series, the authors considered it desirable to make some observations in continuation of their researches on quinaldine derivatives. Having treated crude quinaldine with nitrous acid, as formerly described, in order to remove aniline, monethyl-aniline, and tetrahydroxy-quinaldine, the purified substance was subjected to fractional distillation. In addition to quinaldine boiling at 240° , higher boiling fractions were invariably obtained. The platinum salt prepared from the portion of the distillate coming over between 270° and 280° , gave numbers corresponding to the formula for trimethylquinoline $\text{C}_{12}\text{H}_{13}\text{N}$, formed probably by the action of 3 molecules of aldehyde on aniline, thus—

On oxidation with chromic acid the base yields an acid insoluble in water, the investigation of which is still in progress. The question whether this base is related to the aldehyde discovered by Einhorn is not solved by the authors.—D. B.

Ultramarine by the Wet Method. F. Knapp. J. Prakt. Chem. 1885, 32, 375.

THE author shows that ultramarine blue can be prepared in the wet way, similar to that obtained by the usual method. Silicate of alumina is heated with carbonate of soda and sulphur to a certain temperature, and the product digested with a solution of sodium persulphides. The blue obtained in this way does not compare unfavourably with that obtained by the old method. The principal precaution required in the operation is to roast the mixture, when the kaolin is decomposed. The limit between this temperature and that at which the blue is destroyed makes the success of the operation a difficult one. In course of roasting, the colour of the mixture becomes a darker yellow, then a cinnamon brown, and then a red. The brown colour indicates the correct temperature. The presence of sulphide of iron has an injurious effect. Kaolin is scarcely ever free from iron; and sulphur is also contaminated with it.

—J. B. C.

V.—TEXTILES: COTTON, WOOL, SILK, Etc.

A New or Improved Method of applying Waterproofing Material to Pile and other Goods. Bertie Hallett and Thomas Fernely Wiley. Eng. Pat. 5512, May 5, 1885. 6d.

SUCH goods as cannot be conveniently rendered waterproof by the ordinary methods, are treated by the inventors in the following way: A series of jets is so arranged that a blast of air passing through them carries with it a quantity of the waterproofing material, which is deposited on the article in the form of a very fine spray.

—E. J. B.

Improvements in Apparatus for treating Fibres, Yarns, and Textile Fabrics. C. D. Abel. From Julius Otto Obermaier. Eng. Pat. 6593, May 30, 1885. 8d.

THE present invention relates to a method and apparatus patented by Obermaier in 1883, 2181. The dyeing vessel there described is in the present instance arranged so as to fit on to the shaft of a centrifugal machine. In this way nearly the whole of the superfluous solution can be readily removed, and a fresh one substituted without necessitating the removal of the material. The specification is accompanied by drawings.—E. J. B.

Improved Apparatus to be employed in Washing, Soap-ing, Dyeing, and Darning Woven Fabrics. William Birch. Eng. Pat. 1424, February 1, 1886. 6d.

THIS invention relates to an improvement in the construction of the rollers over which cloth is passed when it is desired to impregnate it with various solutions. A series of longitudinal grooves is cut in the rollers, and

FIG 1

filled with strips of indiarubber (Figs. 1 and 2). The strips are connected by short pieces placed at right angles, thus forming a series of rectangular compartments. The tension of the cloth passing over the rollers compresses the rubber strips, and forces the solution, which has been taken up by the compartments, into the cloth, which is in this way thoroughly impregnated.—C. F. C.

VI.—DYEING, CALICO PRINTING, PAPER STAINING, AND BLEACHING.

The Influence of Artificial Bleaching in Turkey-red Dyeing. P. Lukinoff. Dingl. Polyt. J. 259, 97.

THE author's experiments showed that the Turkey-red on cloth which had been bleached by oxidising agents (bleaching powder solution) was, although very pure, not so full in colour as on unbleached cloth. He thinks this may be ascribed to the formation of Witz's oxycellulose, and Cross and Bevan's basic oxycellulose; and whereas the former serves as a mordant for aluminium hydrate, it acts at the same time like a colloidal substance, preventing the fixation of other mordants, such as fats and tannates, on the same fibre. Cross and Bevan's oxy-cellulose is, as is well understood, a direct preventative to the fixation of aluminium hydrate. Consequently, the fixation of the mordants necessary for the formation of a Turkey-red lake, proceeds on the oxidised fibre less readily, and this appears to be the reason that the colour does not come out full enough.—S. II.

The Use of Antimony Oxalate as a Mordant. C. Bötsch. Chem. Zeit. 9, 1787.

DR. LAUBER recommends the employment of chalk, together with antimony oxalate, to neutralise the acid oxalate of potassium. On the assumption that the chalk is added to the oxalate of antimony previous to the addition of the acid potassium salt, the author points out that calcium oxalate, antimony oxide, carbonate of potassium and free CO_2 , would be formed. The K_2CO_3 formed would act upon a further quantity of antimony oxalate, and precipitate it as basic salt. If the chalk be added when the acid oxalate of potassium is formed, the latter will be neutralised and precipitated. The use of chalk is, therefore, to be condemned.—J. B. C.

Antimony Oxalate. Chem. Zeit. 10, 148.

AT a meeting of the Société Industrielle de Mulhouse, Weber said that antimony oxalate and oxide, as recommended by Kertesz, have given rise to a great number of investigations, unfortunately with very conflicting results. After repeating his own experiments he is able to confirm his statement that both antimony compounds are very suitable for the fixation of tannin.—S. II.

Paraxyloquinoline. Chem. Zeit. 10, 148.

AT a meeting of the Société Industrielle de Mulhouse (Jan. 13, 1886), Nolting gave some details on paraxyloquinoline. The dicarboxylic acid, $\text{C}_6\text{H}_5\text{N}(\text{COOH})_2$, crystallises from alcohol, is nearly insoluble in water, slightly soluble in absolute alcohol, and melts at 290°C . with decomposition. The acid has also basic properties. Its platinum com-

FIG 2

pound, $(\text{C}_6\text{H}_5\text{N}(\text{COOH})_2\text{HCl})_2\text{PtCl}_4$, forms yellow needles, soluble in water and alcohol. On sulphonating paraxyloquinoline, the sulphonic acid, $(\text{CH}_3)_2\text{C}_6\text{H}_3\text{N}.\text{SO}_3\text{OH}$, is formed, crystallising in white prisms, which are easily soluble in dilute acetic acid, but only slightly soluble in water. The same acid is obtained on heating xylidine sulphonic acid, $\text{C}_6\text{H}_2(\text{CH}_3)_2(\text{NH}_2)(\text{SO}_3\text{OH})[\text{CH}_3 : \text{CH}_3 : \text{NH}_2 : \text{SO}_3\text{H} = 1 : 4 : 3 : 5]$, with glycerol and sulphuric acid, whereas an isomeric acid is obtained from $\text{C}_6\text{H}_2(\text{CH}_3)_2(\text{NH}_2)(\text{SO}_3\text{OH})[\text{CH}_3 : \text{CH}_3 : \text{NH}_2 : \text{SO}_3\text{H} = 1 : 4 : 3 : 6]$, which crystallises in white needles, easily soluble in hot water.—S. II.

VII.—ACIDS, ALKALIS, AND SALTS.

Manufacture of Sodium Chromate and Bichromate. N. Walberg. Dingl. Polyt. J. 259, 188.

Manufacture of Sodium Chromate.—Six parts finely-powdered chrome ore ($44\frac{1}{2}\% \text{CrO}_3$), three parts soda ash ($92\% \text{CO}_2\text{Na}_2$), and three parts chalk, are heated for 5 hours in a reverberatory furnace, which holds a charge of 1 ton at a time. The hot mass is lixiviated systematically in order to produce a liquor of 45°B , which is boiled down in iron pots to 52°B , and allowed to cool in lead-lined tanks, where yellow crystals are deposited, having the composition $\text{CrO}_4\text{Na}_2 \cdot 10\frac{1}{2}\text{H}_2\text{O}$. They are dried at first in a centrifugal machine, and then at a temperature of 30°C , in a drying chamber, where they lose their water of crystallisation, crumbling to a yellow powder of the

composition : $\text{CrO}_3 \cdot \text{Na}_2$, 96.60 ; $\text{SO}_4 \cdot \text{Na}_2$, 0.92 ; insoluble, 0.40 ; water, 1.28.

Manufacture of Sodium Bichromate.—Sodium bichromate being more deliquescent the purer it is—that is to say, the more chromic acid it contains—the author prefers to manufacture a product containing no more than 72.5% CrO_3 , which can be packed in wooden casks. The monochromate crystals, previously mentioned, serve as a raw material. The monochromate solution cannot be directly treated with sulphuric acid for the conversion into bichromate, owing to the partial formation of chromium chromate, which spoils the appearance of the finished bichromate. The monochromate crystals are dissolved in boiling water, until a solution of 40° B. is obtained. Oil of vitriol (chamber acid) is then added in such quantity as to convert the neutral into the acid salt, the end of the reaction being readily determined by potassium iodide starch paper. Neutral salt is then added to the hot liquor, in sufficient quantities to obtain a finished product containing 72½% CrO_3 . The liquor, which now contains sodium sulphate, and the neutral and acid chromate, is allowed to cool in lead-lined tanks, where the sodium sulphate crystallises out. In winter the temperature of the air is sufficiently low, whereas in summer recourse must be had to artificial means of cooling to reduce the temperature to at least 1° C. The mother-liquor is then siphoned off, if necessary filtered, and boiled down to dryness in an iron pot, stirring all the time. The mass consists of hard lumps, which must be ground while in a hot state. The bichromate, thus prepared, forms an orange powder, testing as follows :—

CrO_3	72.50	} corresponding with {	$\text{Na}_2\text{Cr}_2\text{O}_7$	81.59
Na_2O	25.20		NaCrO_4	16.08
SO_3	1.40		Na_2SO_4	2.23
Cl.....	trace			
Insoluble.....	trace			
Water.....	0.10			

—S. H.

Note on Malic Acid. H. J. van't Hoff, jun. Ber. 18, 2713—2714.

Inactive Malic Acid from Monobromosuccinic Acid.—The malic acids obtained both by the author (Ber. 18, 2170) and by Anschütz, from monobromosuccinic acid, are identical with that prepared by Pasteur from aspartic acid, as shown by the form of the crystalline acid ammonium salt. The author prepared his bromosuccinic acid from fumaric acid and hydrogen bromide.

Inactive Malic Acid from Maleic Acid.—The author has obtained an inactive malic acid by the action of sodium and water on maleic acid, in the same manner that Lloyd prepared his inactive acid from fumaric acid. The acid ammonium salt crystallised in the same form as that mentioned above.—S. Y.

The Limit of Decomposition of Sodium Carbonate into Caustic Soda by means of Lime. G. Lunge and J. Schmid. Ber. 18, 3286—3289.

THAT the quantity of caustic potash formed by the action of lime upon the carbonate depends upon the concentration of the solution, has long been known. The authors have studied the question in the case of soda. In the soda industry it is well known that complete decomposition of carbonate into caustic soda never occurs. To effect this more completely, Parnell and Simpson patented a method of operating under pressure. This method has not been practically very successful. The authors' experiments were carried out as follows : Solutions of pure carbonate of soda of different degrees of concentration were heated in iron vessels to boiling for one hour with excess of lime, the water as it evaporated being replaced. With increased pressure, copper tubes, with covers to screw on, were used. The agitation of the liquid was effected by pebbles placed in the tubes, which were heated in a suspended air-bath, capable of swinging backwards and forwards. The analysis of the liquid was made for the total alkalinity with methyl orange as indicator, for the causticity with phenolphthalein, according to Winkler's method.

A. Ordinary pressure :—

Before Causticising.		Sp. gr.	After Causticising.		NaOH from 100 parts Na_2CO_3 .
Percentage Na_2CO_3			I.	II.	
2	1.022 at 15°	99.4	99.3
5	1.052 ..	99.0	99.2
10	1.107 ..	97.2	97.4
12	1.127 ..	96.8	96.2
14	1.150 ..	94.5	95.4
16	1.169 at 30°	93.7	94.0
20	1.215 ..	90.7	91.0

B. Increased pressure, at a temperature of 148—153° :—

Before Causticising.		Sp. gr.	After Causticising.		NaOH from 100 parts Na_2CO_3 .
Percentage Na_2CO_3			I.	II.	
10	1.107 at 15°	97.06	97.5
12	1.127 ..	96.35	96.8
14	1.150 ..	95.6	96.6
16	1.169 at 30°	95.4	94.8
20	1.215 ..	91.66	91.61

The above results show that on the laboratory scale the use of increased pressure has no advantage. These results agree with the experiments of Jurisch, who employed Parnell and Simpson's system on the large scale.—J. B. C.

A New Source of Citric Acid. Amer. Druggist, 1886, 12.

THE red bilberry contains besides 0.2 to 0.3 per cent. of malic acid, from 1.5 to 1.75 per cent. of citric acid. The latter can be obtained as follows :—The berries are crushed in a mill and pressed. The press-cakes are ground with water and pressed a second time. The united juices are precipitated with gelatine, which causes a copious precipitate of tannate and dyestuff. The filtrate is saturated with chalk, heated to boiling, and after collecting the white flakes of calcium citrate, the latter is decomposed in the usual manner. If large quantities of berries are to be had, the manufacture of malic acid and sugar can be taken up at the same time.—S. H.

A Method of Manufacturing Oxide of Iron and obtaining other Useful Products. Thos. Bayley, Birmingham. Eng. Pat. 4228, April 7, 1885. 6d.

METALLIC iron or sulphide of iron is dissolved in hydrochloric acid, the resulting hydrogen or hydrogen sulphide being utilised, and the chloride of iron produced is precipitated by milk of lime alone, or mixed with yellow liquor (made by lixiviating the Leblanc alkali waste), which consists of solutions of alkali earth (or, if preferred, alkali), sulphides and sulphhydrates. The precipitated iron hydroxide and sulphide are washed and separated by the filter-press, and the cakes coloured by roasting; the sulphur dioxide being led into vitriol chambers. Oxidised ores are first reduced and the metal treated as above, the solutions being first filtered from insoluble residue.—W. G. M.

Improvements in the Treatment of Bicarbonate of Soda for obtaining Useful Products therefrom. H. Gaskell, jun., Widnes. Eng. Pat. 4274, April 7, 1885. 8d.

THIS invention relates to the treatment of sodium bicarbonate made by the ammonia soda process, which is always impregnated with ammonia. The bicarbonate is dissolved in water at or near the boiling temperature, and the solution boiled until it is free from ammonia. During the process of boiling, steam, ammonia, and carbon dioxide are given off, which are separated by condensation. The solution of sodium carbonate thus obtained may be allowed to crystallise for the manufacture of ordinary soda crystals, or worked up for the production of mono-hydrated carbonate of soda, soda ash, caustic soda or bicarbonate of soda.—S. H.

Improvements in and in Apparatus for the Manufacture of Carbonate of Soda and Caustic Soda. C. Wigg, Liverpool. Eng. Pat. 4436, April 10, 1885. 8d.

THIS invention relates to combination of apparatus suitable for the manufacture of soda by the ammonia

soda process. It consists essentially of carbonic acid generators and purifiers with saturators, carbonators, filters, furnaces and apparatus for recovering and removing carbonic acid and ammonia. The specification is illustrated by five diagrams.—S. II.

Improvements in the Manufacture of certain Chromates and Acid Chromates. J. Broek and W. A. Rowell, Widnes. Eng. Pat. 5260, April 28, 1885. 6d.

CRUDE sodium chromate is first manufactured in the usual manner and afterwards converted into strontium chromate by precipitation with any suitable strontium salt. This strontium chromate, a nearly insoluble body, is then boiled with a solution of ammonium bisulphate, sodium bisulphate, potassium bisulphate, or aluminium sulphate or bisulphate, according as it is desired to produce ammonium, sodium, potassium, or aluminium bichromate. A mutual decomposition takes place, sulphate of strontia being precipitated. If it be desired to manufacture neutral chromates by this process, strontium chromate is boiled with the sulphate of the base required. But as the normal sulphates of ammonia, soda and potash do not completely decompose strontium chromate with equivalent proportions, it is preferable to use the acid salt and afterwards neutralise the corresponding quantity of free chromic acid existing in the solution. The same reaction can also be applied to the purification, from sulphuric acid or sulphates, of solutions of chromates of the bases named or their bichromates or acid chromates, made by other processes.—S. II.

An Improved Process for the Manufacture of Ammonium Chloride and Potassium Sulphate. W. R. Lake, London. From Schmidtborn and D. Jarves, New York and Michigan, U.S.A. Eng. Pat. 12,745, October 23, 1885. 4d.

The invention depends on the reaction of ammonium sulphate on potassium chloride when present in equivalent proportions. A mutual decomposition takes place—thus: $(\text{NH}_4)_2\text{SO}_4 + 2\text{KCl} = \text{K}_2\text{SO}_4 + 2\text{NH}_4\text{Cl}$. Potassium sulphate may then be separated by "salting out."

—S. II.

VIII.—GLASS, POTTERY, AND EARTHENWARE.

Seeger Porcelain. Ztschr. d. Ver. D. Ing. 1885, 29, 578.

THIS manufacture may be regarded as the latest step in the progress of this industry. As the temperature only reaches 1500–1600° (hard porcelain requires 1800–2000°) the palette of the colourist is very much extended, and this circumstance also allows of decoration with under-glaze colours. The choice of coloured glazes is practically unlimited, and amongst these especially rose tints of all shades are readily attainable. Ornamentation with thick coloured enamels is in so far perfected that the burning temperature has been lowered to that of the muffle colours, so that both can now be burnt at one firing. Seeger has further succeeded in producing Chinese red (copper red), a glaze which has only been obtained in some factories in Nankin.—J. B. C.

IX.—BUILDING MATERIALS, CLAYS, MORTARS, AND CEMENTS.

Manufacture of Cement from Furnace Slags. R. Bosse. Stahl u. Eisen, 1885, 5, 497.

THE puzzolana cement obtained from furnace slag demands increased attention from the fact that the time for setting has been very much diminished. Although the time of setting (about 22 hours) of the puzzolana cement was a valuable property, as it could be more thoroughly worked, it was, on the other hand, a reason against its general adoption because its initial tenacity appeared smaller than that of the Portland cement, the hardening of which occurred in about six

hours. By the method of Wolters and Tetmajer, the time of setting of the puzzolana cement is very much diminished and its tenacity increased.—J. B. C.

X.—METALLURGY. Etc.

Influence of Aqueous Vapour upon the Oxidation of Hydrogen. W. Muller-Erbach. Ber. 18, 3239–3240.

IN a previous communication the author has shown that the temperature of reduction for hydrogen is very much increased in absence of aqueous vapour—e.g., in the case of precipitated oxide of iron from 45° to 285°. The attempt was made to dry the hydrogen in a tube containing CaCl_2 , which, however, as the author has since found, does not perfectly dry the gas. It therefore appears that partial drying of hydrogen decreases its power of reduction. When specular iron ore was heated with hydrogen in presence of CaCl_2 , a considerable quantity of hydrogen, varying with the time of heating, remained unabsorbed. Hammer slag, which readily gives up its oxygen, oxidised nearly all the hydrogen, whereas with moist hydrogen this is not to the same extent the case. The action of aqueous vapour in promoting oxidation consists—firstly, in lowering the temperature of reduction, and in the second place in producing much more rapid reduction. It is still doubtful if in the experiment with specular iron the dilution of the hydrogen is of importance; but the author having found that the water taken up by the CaCl_2 is very slowly absorbed into the inner portion of the salt, and that its minimum tension is thus only reached after a long time, he is led to conclude that the modified action of the hydrogen is due to the decrease in quantity of aqueous vapour present. Mixtures of oxygen or nitrogen act upon moist hydrogen, and nitrogen upon moist carbon monoxide, in a manner similar to that of the dehydration of the gas, as they produce an increase in the temperature of reduction. The action of aqueous vapour appears, therefore, to be opposed to that of oxygen and nitrogen. The behaviour of a dry mixture of hydrogen with oxygen or nitrogen should however be determined.—J. B. C.

Improvements in Coating with Tin, Terne, or other Coating Metal, Sheets, Plates, or Pieces of Iron or other Metal. Edmund Morewood, Llanelly, Carmarthen. Eng. Pat. 3738, March 23, 1885. 11d.

THIS patent relates principally to the removal of scruff or dirt from the coating material and the coated plate. Before passing to the finishing rollers, which work in melted grease as in the usual arrangement, the plates are drawn between cleansing brushes consisting of long surfaces of iron wire, hard wood, brick free from grit, or preferably of tinned iron plate, to which a rapid reciprocating motion is imparted by a pair of eccentrics; beneath each brush is a trough or wash hole to receive the scruff removed, the brush being perforated to allow the dirt to pass through it. In hand brushing the plate is forced by means of a pair of tongs between two hempen brushes, with an adjustable distance between them. Where the plates are removed from the tin-pot horizontally, the excess of surface tin is removed, after traversing a pair of mechanical brushes, by passing between a pair of small tinned rollers working within, and actuated by frictional contact with, a pair of outer rollers also tinned; the excess tin is thus transferred from the plate to the inner rollers, which, in turn, convey it to the larger ones, and by these it is returned to the pot. Conversely, if a thick coat of tin be required, the outer rollers run in a trough of tin, and thus by the aid of the inner pair convey the metal to, instead of from, the plate. Excess of tin and scruff may be removed from the rollers themselves by fixed or movable brushes with wash holes beneath. The surface of the metal bath is freed from dross by a mechanical scraper, which from time to time skims across the metal and carries the dirt into a wash hole placed at the side. A system of coating each plate separately is

also described. Two reservoirs of tin are arranged side by side, in the farther one a number of rollers with brushes work in melted grease, and beneath each pair of brushes is a long narrow trough, these troughs being continued to the first or feeding chamber, but they are contracted at the point of junction to a slit only wide enough to just pass the plate. Between the reservoirs a mechanical scraper, as above described, removes the scum. The plates are fed singly into these troughs, and thus pass out singly to the finishing rollers.

—W. G. M.

Improvements in Treating Waste Liquors from the Manufacture of Tin Plates. W. E. A. Hartmann, Swansea. Eng. Pat. 4478, April 8, 1885. 6d.

THE waste pickling liquors, consisting for the most part of ferrous chloride with an excess of hydrochloric acid, are mixed with caustic magnesia in excess (or with magnesium carbonate and magnesia), whereby magnesium oxychloride is formed, causing solidification of the mass: this mass is then air- or kiln-dried, and finally fired at a red heat, the evolved hydrochloric acid being recovered in condensing towers. The residue consists of ferric oxide and magnesia, which are again used for precipitating a fresh charge; it is used again and again until the contained percentage of magnesia is inconveniently small, when it is treated with an excess of acid liquor and the whole of the magnesia dissolved, the ferric hydroxide being left pure and convertible into the anhydrous oxide.—W. G. M.

An Improved Process for the Manufacture of Iron and Steel direct from the Ore with Gaseous Fuel, and Apparatus employed therein. F. J. P. Cheesbrough, Liverpool. Eng. Pat. 4744, April 17, 1885. 8d.

AT the base of a blast furnace and communicating directly with it, are two open-hearth reverberating furnaces, the gases for which are supplied from a bench of gas producers, the air being heated, as in ordinary practice, by hot-blast stoves. Ore, flux, and coal or coke are charged in as usual—the coke serving to keep the mass open—and the molten metal, instead of collecting in the crucible of the furnace, is run directly and alternately into the open-hearth furnaces, where it may be worked on a basic lining, and after the manner of the Siemens process; or, if foundry pig be required, it may be tapped as required in the usual way. When steel is desired, water gas is employed; otherwise producer gas may be used. If phosphorus be present in any quantity a larger quantity of lime is added with the flux, and yet more is added in the reverberatory furnace. The burnt gases from the open hearths pass to the blast furnace by the channel which conveys the melted metal from it, and are there, by the action of the carbon, reconverted into reducing gases capable of acting upon the ore in the higher zones of the furnace. The requisite pressure is provided by an exhaust fan rather than by the usual blowing engines.—W. G. M.

An Improved Process for Purifying Copper Precipitates. J. Y. Johnson, Lincoln's Inn Fields. From Ernest Deligny, Paris. Eng. Pat. 8418, July 11, 1885. 6d.

FOR the removal of the antimony and arsenic which exist as metallic antimonites and arsenites in the precipitated copper, the precipitate is heated in a concentrated solution of an alkaline nitrate, whereby these salts become peroxidised; the resulting insoluble antimonates and arsenates are next heated with constant agitation in a solution of caustic alkali in a series of vessels, into which the precipitate is fed at one end and gradually transferred to the other, meeting the alkali solution which travels in the reverse direction; thus, the almost pure copper in the last vessel is acted upon by the fresh caustic liquid. By the action of the alkali the antimony and arsenic are removed as soluble salts, leaving instead precipitated metallic oxide with the copper, which may now be finally purified by washing. The alkaline solution

may be used again after treatment with caustic lime, which precipitates the antimonates and arsenates. If preferred, a dry method may be employed. The crude precipitated copper is heated to dull redness with a sufficient quantity of an alkaline nitrate, which oxidises the impurities as above, and becomes converted into free alkali, thus completing the reaction in the same stage; it only remains, then, to lixiviate the mass and collect the purified copper.—W. G. M.

XII.—PAINTS, VARNISHES, AND RESINS.

Improvement in Vulcanising Soft Rubber, and Process of Making the same. F. Willhöft, New York. Eng. Pat. 7914, June 30, 1885. 6d.

THE defects of all vulcanised goods now manufactured are due to an excess of sulphur, which effloresces, causing "bloom," and also eventually renders the goods brittle, the large quantity of sulphur, 6–12 per cent., being necessary on account of the temperature (280–300° F.) at which vulcanisation is ordinarily effected. By the use of a temperature of 330–350° F. the patentee claims to be able to effect complete vulcanisation of the rubber without an excess of sulphur, of which he uses 3½–5 per cent. The heating is effected by means of steam at 112lb. pressure, and the whole process only requires about one-third the time usually taken.—E. E. B.

XIII.—TANNING, LEATHER, GLUE, AND SIZE.

The Preparation of Skins, Kips, and Hides, by an Improvement in the Process known as "Puring" or "Bating." Alfred James Hailes. Eng. Pat. 457, January 12, 1886. 4d.

THE skins, kips, or hides are immersed in a bath of acetic acid, with or without chlorhydric or other acid or acids, and treated precisely as in the ordinary process of "puring." The strength of the bath is entirely dependent on the quality of the skins and their mode of preparation.—B. H.

Manufacture of a Substitute for Caoutchouc and Gutta-percha. A. M. Clark, London. From J. J. Hang and C. Hoffmann, both of St. Petersburg. Eng. Pat. 1108, January 25, 1886. 4d.

UNHAIRIED skins are digested with 5 per cent. of glycerine (crude) and a minimum of water in a Papin's digester until complete solution is effected. The thick, tenacious mass thus obtained is treated with an equal quantity of glycerine and one-twelfth of its weight of a concentrated solution of potassium bichromate, potassium chromate, or equivalent substance; it is then poured into moulds, left to solidify under pressure, and finally dried in an airy dark room. The product is similar to caoutchouc, but withstands heat much better; it may be rendered acid- or water-proof, very elastic or as hard as glass by altering the above proportions and adding various substances.

—E. E. B.

XIV.—AGRICULTURE, MANURES, Etc.

Notes on Grinding Thomas-slag. Horn. Berg. u. Hüttem. Ztg. 1886, 45, 40.

THE principal difficulty in grinding Thomas-slag is the presence of metallic iron. After many experiments, the author comes to the conclusion that it is best to crush the slag roughly in roller-mills and sort it afterwards in slanting sieves (Nagel and Kämp's patent). By this means the iron can be removed. The disintegration to a very fine powder may then be performed in horizontal mills. A large works for grinding Thomas-slag is now in course of construction at Ruhrort, Westphalia (Phenix).—S. H.

Manurial Experiments with Slag from Thomas-Process. H. Bieler, jun. Bied. Centr. 15, 29–30.

EXPERIMENTS were conducted with oats, on medium heavy loam, the crop of the previous year being carrots

manured with stable manure. In the one case the slag, in conjunction with nitrate of soda, did not prove economical; whilst in the other experiment, in conjunction with nitrate of soda and kainite, it did so.—D. A. L.

Durability of the Germinating Power of Beet-root Seeds.
G. Marck. Bied. Centr. 15, 54—58.

THE author's experiments with fresh and old beet-root seeds indicate the following as the order of excellence with regard to germinating power:—1st and best, seeds one year old; 2nd, seeds three and four years old, about equal; 3rd, seeds freshly gathered and two years old. Seeds five years old and older show a marked and increasing decrease in germinating power. Arranged numerically they stand as follows: Of seeds up to four years old, 90—100 per cent. germinate; of seeds five to seven years old, 45—55 per cent.; whilst of seeds nine years old, only 24 per cent. germinate.—D. A. L.

Occurrence of Coniferin and Vanillin in Asparagus.
E. O. v. Lippmann. Ber. 18, 3335—3336.

THE peculiar after-taste of vanillin, which asparagus (especially the preserved vegetable) imparts, led the author to examine it for this substance. The same method was adopted as that employed in isolating it from the sugar-beet. In this way the author succeeded in separating a small quantity of vanillin and a much larger amount of coniferin, both of which were identical in physical properties with the bodies prepared from other sources.—J. B. C.

XV.—SUGAR, GUMS, STARCHES, Etc.

The Monostrontium-saccharate Process. C. Scheibler.
Neue Ztschr. f. Zucker-Ind. 1886, 16, 1.

MOLASSES are treated with so much of a hot saturated strontium hydrate solution that for each part of sugar one part of strontium oxide is present. After the solution is complete the mass is allowed to cool and stand for three to six hours in order to crystallise out the monosaccharate. The latter is separated by filter-presses, washed with a small quantity of water or juice, carbonated, and the 20 per cent. sugar solution thus obtained worked up as usual. The mother-liquor of the monosaccharate, which still contains about 30 per cent. of sugar, is treated with so much strontium hydrate that for each part of sugar there are three-and-a-half parts of the hydrate, boiled for eight to ten minutes and allowed to stand. Bisaccharate falls down, and is mixed with so much molasses that a monosaccharate solution is formed, which is treated as previously described. The strontium carbonate resulting from the carbonation is decarbonated, and serves again for the formation of the monosaccharate. It is claimed for this process that it yields concentrated juices, and no raffinose being formed, it is said to be the cheapest and simplest of all processes for the recovery of sugar from molasses.—S. H.

The Manufacture of Maltose. Neue Ztschr. f. Zucker-Ind. 1886, 16, 32.

ONE part of green or partially-dried malt is warmed with two to three parts of water, digested for several hours at 30° C., and afterwards filter-pressed to obtain an "infusion" of malt. One part of starch-flour is then suspended in two to twelve parts of water and 5 to 10 per cent. of infusion, the whole gradually warmed to 80° C., then heated under a pressure of 14 atm. for thirty minutes, quickly cooled to 45° C. and treated with 5 to 20 per cent. of infusion and hydrochloric acid (from 6 to 25 cc. HCl per 100 litres). After one hour the mass is filtered through filter-paper fastened or cemented upon linnen-cloth. The solution is allowed to stand at 48° C. for twelve to fifteen hours, then concentrated to 25° B., filtered, again concentrated to 35° B., filtered through animal charcoal, and allowed to crystallise.—S. H.

Process for the Recovery of Sugar from Molasses.
Sucrerie Indigene, 1886, 27, 5.

100 KILOS. molasses are mixed with 150 litres of alcohol, containing 5 per cent. of sulphuric acid. Sulphates are precipitated, which are filtered, some benzene being added to the filtrate. Sugar is deposited in a very pure state in the form of a heavy syrup. The latter is washed with a mixture of alcohol and benzene, and then concentrated without further purification. Benzene is separated from alcohol by the addition of water, and both benzene and alcohol are recovered by distillation.—S. H.

Improved Scheibler Apparatus for the Extraction of Sugar from Beet. C. Scheibler. Bied. Centr. 15, 71 (Zeits. Rübenzucker, Ind. 14, 286—287).

THE object of the present improvement in this apparatus is to prevent the condensed spirit percolating too rapidly through the root-mass, and in this way to ensure more perfect extraction. Previously, the spirit, after percolating, passed into a second open tube (a jacket-tube) and thence into the flask. It is now proposed to close this second tube at the lower end, to pierce it with holes above the level of the root-mass in the inner tube, and to envelope it in a third tube connected with the flask. When the improved apparatus is in operation the root-mass, by means of the suggested modification, is kept constantly covered with spirit, and is hence more likely to be well extracted.—D. A. L.

On the Raffinose or Melitose obtained from Molasses, Cotton-seed, and Eucalyptus-manna. P. Rischbiet and B. Tollens. Ber. 18, 2611—2616.

THE isolation of a sugar of high rotary power from molasses has been already described by Tollens (this Journal, 1885, 290—291; Ber. 18, 26), and its similarity to Loiseau's raffinose and Ritthausen and Böhm's sugar from cotton-seed was then pointed out. The results described have been confirmed by Loiseau and by Scheibler, who, however, proposed the formula $C_{18}H_{32}O_{16} + 5H_2O$ for the sugar, instead of that adopted by Ritthausen and by Tollens— $C_{18}H_{32}O_{16} + 3H_2O$.

The properties of the raffinose from both molasses and cotton-seed have been carefully investigated by the authors, and their identity established. The rotary power $[\alpha]_D$ is 104—104½°, but after warming with acid for a short time, 48—49°. Raffinose ferments readily with yeast, and yields nearly the same quantity of alcohol as cane-sugar. By continued heating with acid, levulinic acid was obtained; the phenylhydrazine compound was prepared, and the reducing power of inverted raffinose was estimated with Fehling's solution, and was found to be less than that of dextrose. The loss of water on heating to 70—80° was 14.5—15 per cent., corresponding to the formula $C_{18}H_{32}O_{16} + 5H_2O$; but at 100° more water was given off, so that some doubt may exist as to the true amount. In moist air all the water is again taken up. With caustic soda and alcohol, raffinose yields a compound containing 6 to 7 per cent. of sodium, the formula $C_{18}H_{32}NaO_{16}$ corresponding to 6.32, and $C_{18}H_{32}O_{16}.NaOH$ to 6.02 per cent. of that metal.

By oxidation with nitric acid, raffinose was found to yield from 22—23 per cent. of mucic acid, while galactose gives 74—77, and milk-sugar 36—38 per cent. The formation of this amount of mucic acid is a strong argument against the formula $C_{18}H_{32}O_{16} + 3H_2O$, but agrees with the other, $C_{18}H_{32}O_{16} + 5H_2O$, if it be assumed that a molecule of raffinose contains one galactose group ($C_6H_{12}O_6$). On the other hand, a monosodium compound corresponding to the second formula would contain 4.23—4.37, and a disodium compound 7.88—8.38 of sodium, the amount found being 6—7 per cent. It is therefore probable that the molecular weight is higher than is expressed by either formula. All the facts could be explained by adopting the formula $C_{36}H_{64}O_{52} + 10H_2O$, and the rotary power of inverted raffinose might be deduced from it by taking account of the various bodies formed—galactose, levulose, dextrose, and a dextran or dextrin group. The dextran or dextrin group would, while present, prevent the crystallisation of the inversion

products, and its conversion by the continued warming of raffinose with acid into glucoses would account for the gradual decrease of rotary power.

Of the other products the authors believe that they have isolated galactose and levulose, and possibly dulcitol.

Melitose from Eucalyptus-manna, by B. Tollens.—Having obtained 22.5 grms. of the manna from Baron F. v. Müller, in Melbourne, the author investigated this compound, and by careful purification obtained 10.5 grms. of melitose from 20 grms. of the crude substance. The percentage of water was found to be 14.67, and the rotary power 104.00—104.44° for (α)_D at 20°. The identity of raffinose and melitose is thus proved, and the older name, melitose, may now be applied to the sugar from all these sources.—S. Y.

XVI.—BREWING, WINES, SPIRITS, Etc.

Improvements in Apparatus for Heating Wine and other Liquids. A. Browne, Middlesex. From A. Fromm, M. Ballo, and F. T. Kugler, Buda-Pesth, Hungary. Eng. Pat. 1851, February 10, 1885. 8d.

THIS is an apparatus for Pasteurising wine or other liquids, and generally for heating water for household or other purposes, to a temperature less than 100° C. It consists of a coil, heated either by a fire direct, or immersed in a jacket of hot water, through which the wine or other liquid is made to circulate by an arrangement of tubes inserted in the bung-hole of the cask. It is claimed that the apparatus fulfils all requirements both of theory and practice—viz., that the wine shall be heated from below; that the wine, once heated, shall not come in contact with the air; and that the wine shall not come into contact with surfaces heated to 100° C.—G. H. M.

Improvements in the Manufacture of Beer and Malt Liquors, and in Apparatus for the Treatment and Preparation of Materials for the same. W. Lawrence, London. Eng. Pat. 4068, March 31, 1885. 11d.

THIS is a process for treating malted grain in such a way that in the process of brewing a beer is obtained which is entirely unlike either the English "top-fermentation" beer, or the Lager "bottom-fermentation" beer. The process includes improvements in grinding the malt, in mashing and straining the wort, and in fermenting the same. The mash is made with the help of an injector (Eng. Pat. 4277, 1882, and 1205, 1883), which mechanically bursts the starch granules of the malt at a low temperature, 100—115° F., and consequently allows the diastatic action to run down to a lower point with the formation of a low dextrine. The fermentation is carried on with a small quantity of yeast, preferably "French" yeast, and in small vessels. The resulting beer, which the inventor styles "distinctive" beer, is said to be free from acidity, to possess good keeping properties, to be highly stimulating, but much less intoxicating than ordinary beer, and, at the same time, digestive. A full description of the plant used, which includes a modified grinding arrangement, special mash-tun, filtering apparatus, and fermentation vessel, are described in detail, and directions are also given for a complete brew on the inventor's system.—G. H. M.

Improvements in Apparatus for Raising Beer. W. J. Chadwick, Salford. Eng. Pat. 4380, April 9, 1885. 8d.

THIS is an apparatus to be used instead of pumps for raising beer from one level to a higher level; for instance, from a cellar to the place of consumption. For this purpose a pressure of air, or preferably carbonic acid gas, is obtained by connecting a close chamber with a reservoir of water, placed at a sufficient height to give the required pressure. When carbonic acid gas is used, it is necessary to either use oil in the reservoir, or cover the water in the close chamber with a layer of oil, in order to prevent absorption of the gas by the water. The carbonic

acid gas is generated in an apparatus connected with the close chamber under sufficient pressure to force the liquid back into the reservoir. The gas space in the chamber is connected with the casks of liquid in the ordinary way.—G. H. M.

Modes of Treating and Utilising certain Waste Products obtained in Brewing and Similar Processes. J. C. Mewburn, London. From G. Noback and Dr. W. Gintl, Prague, Bohemia. Eng. Pat. 6243, May 21, 1885. 6d.

THIS consists of a process for easily recovering the bitter and resinous matters of hops from the various sediments and deposits occurring in brewery vessels, and also from spent hops. These sediments, etc., are dried either atmospherically or by the aid of heat, and then thoroughly extracted with hot strong alcohol. The alcoholic extract is allowed to cool, filtered, and the alcohol distilled off. The residue from the alcohol is then successively treated with sodium carbonate solution until nothing more is taken up. The residue is then dried and constitutes *hop resin*. The sodium carbonate solution is precipitated with acid, and the light yellow precipitate obtained filtered off and washed with water; this substance is the *hop bitter*, and may be used to replace a portion of the hops in brewing, and also to increase the "foaming" power of beer. The hop resin may also be used in beer, as well as for preparing a varnish for brewing vessels and storage casks.

The preparation of the above substances may be varied by treating the waste products directly with a 5 per cent. solution of sodium carbonate, and subsequent treatment of the residue with wood spirit, carbon disulphide, etc., or by direct treatment of the waste products with the latter solvents.—G. H. M.

XVII.—CHEMISTRY OF FOODS, SANITARY CHEMISTRY, DISINFECTANTS, Etc.

(A) CHEMISTRY OF FOODS.

The Influence of Foods on Digestion. M. Ogata. Chem. Centr. 16, 665.

THE author has arrived at the following results, based upon experiment: Water, carbonated water, tea, and coffee taken moderately, do not influence digestion; beer, wine, and brandy retard at first, until they are assimilated; and with beer, the alcohol as well as the extractive substances have the same effect, which accounts for the fact that beer retards digestion much more than wine containing an equal amount of alcohol. Sugar (cane and grape sugar) slackens digestion; salt has the reverse effect. It has not been determined whether this retarding action has a good effect on the organism, or whether, on the contrary, it is injurious.—J. B. C.

(B) SANITARY CHEMISTRY.

Injurious Action of Factory and Domestic Drainage on Fish and on Fish Culture. C. Wiegelt, O. Saare, and L. Schwab. Bied. Centr. 15, 1—9.

FOR the investigation of this subject, fish were placed in water containing specified impurities in definite quantities, and the effect produced in them was noted. As examples of hardy fish, tench were selected for experiment, whilst delicate fish were represented by trout and salmon. In some cases the fish sickened, but recovered on removal into fresh water; in other cases they sickened past recovery, or died at once; whilst under some other conditions they remained unhurt. Several circumstances affect the results—for example, the species of fish, some withstanding the action of foreign matter better than others. Nevertheless the same impurity produces the same symptoms in individuals of the same species. The heavier and older fish are less susceptible than the smaller and younger ones; and, moreover, the higher the temperature, and the

greater the concentration of the solution, the more potent is the action of the injurious substance; whilst the length of the period of exposure exercises considerable influence on the result. In the following table some of the authors' results are given. The time of exposure, when not otherwise noted, is 24 hours for tench, and 1 hour for trout. If the fish did not expire within three days after treatment, the substance they had been subjected to was deemed harmless. When no kind of fish is specified in the original paper, the entry is marked thus *.

assumed to be of absolute value for pronouncing judgment as to the injurious qualities of any drainage.

—D. A. L.

Improvements in Purifying and Deodorising Sewage, etc.
F. M. Lyte, Putney. Eng. Pat. 900, January 21, 1885. 6d.

THIS specification is that taken out January 21, No. 900, and abstracted in a former number of this Journal, amended. Leave has been granted to its author to

SUBSTANCE EMPLOYED.	Quantities in Parts per 1000.					
	Harmless.		Injurious.		Fatal.	
	Trout.	Tench.	Trout.	Tench.	Trout.	Tench.
Sulphuric Acid	0.05	0.50	0.10 (2-6 hours)	—	—	—
Hydrochloric Acid	—	—	—	—	1.00	1.00
Nitric Acid	—	—	0.10	—	—	—
Sulphurous Acid	0.005	—	0.001	—	0.001	0.001
Carbonic Anhydride	(in one expt)	—	(in one expt)	—	0.10* (immediately)	0.10* (in a few minutes)
Phenol	0.005	0.01	0.05	—	0.01-0.005	0.05-0.01
Chlorine (Chloride of Lime) ..	0.0005 (2½ hours)	0.001 (3 hours)	—	—	0.0008	0.01-0.005
Mercuric Chloride	—	—	—	—	0.05 (immediately)	0.10 (immediately)
Copper Sulphate	} If quickly	transferred to	fresh water	0.101 (at 8° C.)	0.10 (in a few minutes)	1.0 (at 20° C.)
Potassium Cyanide					0.005 (in a few minutes)	0.01 (at 20° C.)
Sodium Sulphide	—	0.1 (30 minutes)	—	0.101 (at 8° C.)	—	0.115 (at 20° C.)
Ammonia	0.01*	—	intermediate	between	chlorine and	the acids
Soda	3.0*	—	5.0 and 10.0 (after 3 hours)	—	1.0 (after prolonged action)	—
Hydrogen Sulphide	—	—	—	—	0.01 and 0.001 (soon)	0.01-0.001
Carbon Disulphide	—	—	—	—	like hydrogen sulphide	—
Iron Salts	—	1.00 (16 hours)	5.0 (3 min.) 1.0 (23 " 0.5 (27 "	—	0.1 (16 hours)	—
Aluminium Salts	0.05	1.00	10.00	—	—	—
Amyl Alcohol	When treated with fresh water		1.00	—	—	—
Tannic Acid	0.1	10.0	10.0 (½ an hour)	—	—	—
Tar	—	—	0.2	10.0	—	—
Calcium Chloride	1.0	10.0 (at 6° C.)	—	—	—	10.0 (at 20° C.)

The following have been found harmless for trout:—Oxalic acid, 0.01 per cent. for half-an-hour; ammonium carbonate, 3.0 per 1000 for half-an-hour; manganous chloride, 1.0 per 1000 for 5 hours; ammonium thiocyanate and potassium ferrocyanide, 1.0 per 1000 for 1 hour. The following for tench: Manganous chloride, 5.0 per 1000 for 22 hours. And for both sulphites, and arsenic acid or sodium arsenate, 0.1 per 1000; glycerol, and oils which cover the surface of the water (tench can exist 20 hours with air excluded), methyl and ethyl alcohol, 10.00 per 1000; sodium chloride 10.00 per 1000. Lime, however, is very injurious, probably from the formation of calcium carbonate in the gills. Suggestions are made, founded on the above results, as to the regulation and mode of treatment of factory refuse and drainage. It is still a question whether by prolonged existence in extremely dilute solutions of injurious substances, the fish do not suffer chronic poisoning. Unimpregnated eggs resist the action of impurities to an extraordinary extent; but impurities, when present in quantities not under 0.1 per 1000, act injuriously on impregnated and fertilised eggs, apparently weakening their power of development. Dilute fermented sewage is extremely injurious to trout, etc.; the injurious effect can be traced to the large quantity of poisonous gases present, and to the deficiency of oxygen, without taking bacteria, etc., into consideration. The authors point out that the above numerical data are not

amend his specification, that the terms in the original specification may be narrowed, so as not to include reagents which it is not desirable to employ.—C. C. H.

An Improved Method of Purifying Drainage Waters and Sewage. M. Nahsen, Schönebeck-a-d-Elbe. Eng. Pat. 5348, April 30, 1885. 6d.

"PHOSPHORIC SLAG" is disintegrated with water into a pulp; from one to two kilogrammes are added to a cubic metre of the sewage. The defecating effect may be increased by the addition, either before or after adding the slag, of dissolved magnesium argillaceous earth, iron or manganese salts. When these latter are omitted, hydrated silicic acid may be added to secure additional clarification, and to correct the alkalinity of the sewage.

—C. C. H.

Improvements in Water Filters. E. Johnson, London. Eng. Pat. 5524, May 5, 1885. 8d.

A BELL-SHAPED vessel with a pear-shaped bulb at the end is inverted over a receiving vessel. The bulb is filled with granulated carbon and "carbon cloth"; the neck of the bulb is stopped with a hollow plug of so-called "feral carbon" filled with carbon cloth, and the lower end provided with a small orifice for the escape of the filtered water.—C. C. H.

An Improved Filter. J. Howie, Kilmarnock. Eng. Pat. 5792, May 9, 1885. 8d.

THIS invention is for an improved form of water filter. The medium is made by mixing together sawdust and clay; two parts of the former and one part of the latter are suitable proportions. This mixture is made into a paste with water, moulded into the desired shape, and burned in a kiln. Sometimes burnt clay, broken biscuitware, asbestos or silicate of soda are added to the mixture. The general form and method of using the filter is similar to those extensively in use, the patentee confining his claims for novelty to the preparation of the porous carbonaceous porcelain ware.—C. C. H.

Improvements in Sewage Purification Processes, etc. F. M. Lyte, Putney. Eng. Pat. 6054, May 16, 1885. 6d.

THIS patent claims improvements on that taken out by the same author, Eng. Pat. 900, January 21, 1885. In the former patent, sewage or water purification was effected by the addition to the sewage or water of a small quantity of a soluble aluminate, preferably sodium aluminate, and it was stated that a small quantity of an acid, a salt of alumina, or any acid salt, should be previously added to produce decomposition of the aluminate and precipitation of the hydrated aluminium oxide. It is now found that other salts, such as calcium sulphate and chloride salts of magnesium or zinc, produce the same result. The patentee therefore claims the use of a neutral earthy or metallic salt in conjunction with a soluble aluminate for the purpose specified; (2) the use of an aluminate for softening waters in which salts of lime or magnesia are already present.—C. C. H.

Improvements in Treating and Drying Excreta, and Manufacturing the same into Manure. W. Grimshaw, Ashton-under-Lyne. Eng. Pat. 6453, May 27, 1885. 4d.

EXCRETA collected by the "Pail system" is mixed in a pug mill with dried excreta and cotton or woollen waste. It is moulded into blocks, dried in a kiln and finally pulverised. The kiln is heated direct with the products of combustion, from a furnace mixed with sulphurous acid gas, and after passing through the kiln, the gases are passed through a deodorising chamber, and thence into a furnace heated to incandescence.—C. C. H.

An Improved Method of Continuous Filtration applicable to the Purification of Sewage, etc. G. H. Leane, London. Eng. Pat. 1053, January 23, 1886. 6d.

A RECTANGULAR tank is divided up by longitudinal walls forming a series of long narrow channels fed by sewage from a common inlet. Inside each of these channels another channel of a smaller sectional area is constructed, having porous sides and a porous bottom. The sewage filters through the porous walls into the interior of the second channel, and runs away from the end of the tank opposite to that at which it entered. The walls of the filtering channel are formed by two sheets of perforated material, iron, wood, etc., packed between with carbon produced from the distillation of Kimmeridge shale. The suspended matters remain on the outside of the filtering channel and are deposited in the space betwixt it and the main chain. The patentee claims the combination of the arrangements as described.—C. C. H.

(C) DISINFECTANTS.

A Method of Disinfecting or Purifying Foul Water. H. J. Haddan, London. From G. Langbein, Leipsic. Eng. Pat. 4714, April 16, 1885. 6d.

AN aqueous solution of sodium nitrite (or any soluble nitrite) of a strength such that 100 litres of the solution contain 69 kilos. of the sodium nitrite, is mixed with an equal volume of dilute sulphuric acid containing 5 kilos. of acid in 1000 litres of water and added to the foul water or sewage. The nitrous acid set free is oxidised

by the atmospheric oxygen, and the hyponitric acid produced acts upon the organic matter present, nitrous acid being again produced; the process is therefore repeated so long as organic matter capable of being oxidised remains present. The patentee states as an advantage that all organisms originally present are destroyed.—C. C. H.

XVIII.—ELECTRO-CHEMISTRY.

The Application of Electricity for Silvering. G. Zinin. Dingl. Polyt. J. 1886, 259, 26.

THE author succeeded in replacing the poisonous silver cyanide bath by another solution, which can be kept without decomposition for any length of time, and is not acted upon by sun-light. The new bath consists of an aqueous solution of silver potassium iodide, and is made up by dissolving 6.66 grms. of silver nitrate in 1000 cc. of water, and adding 500 grms. of potassium iodide. Copper objects are prepared in the same manner as in using the cyanide bath. A plate of pure or alloyed silver serves as anode. The electric current must be very weak, so that no free iodine is deposited on the anode, although free iodine does not spoil the bath, since it can be made to combine again by the addition of a small quantity of potassium hydrate. From ten to thirty minutes are usually sufficient for silvering, and after immersing the silvered object in a bath of one part of potassium iodide in four parts of water, it may be polished. The new bath is more expensive than the cyanide bath, but considering that any thickness of silvering can be produced with the further advantage of far greater expediency and simplicity, it will repay the extra cost for chemicals.—S. H.

Improvements in the Process of and Apparatus for Separating Metals from their Alloys and other Compounds. J. J. Sherlock, Barnet. Eng. Pat. 4829, October 10, 1883. 4d. Received Provisional Protection only.

A STORE TANK, containing a suitable solvent for the metals it is desired to extract, is arranged to supply into a vessel within which is a porous cell. Into this cell the excess solvent overflows, and is constantly removed from beneath to a series of porous walled compartments contained in a depositing tank. The alloy to be treated forms the anode in the inner porous cell to a voltaic current; the more electro-positive metals dissolve and the solution passes to the depositing tank, where in the successive compartments it is submitted to the action of a series of metals each more electro-positive than the last, and so selected that each in order will effect the displacement of one of the dissolved metals without affecting the others. The treated liquid is then to be restored to the store tank.—W. G. M.

Improvements in and relating to Electrical Accumulators, or Secondary Batteries. W. R. Lake, London. Eng. Pat. 2765, March 2, 1885. 6d.

THIS invention relates more particularly to the employment in electrical accumulators, or secondary batteries, of plates composed of chloride of lead with from three to ten per cent. of chloride of zinc or other suitable metallic chloride, thereby preventing breakage of the plates and ensuring great porosity of the mass by the elimination first of the chlorine and then of the zinc or other metal.—W. B.

A System of Photo-telegraphy. W. Gemmill, Kirk-maiden, Wigton. Eng. Pat. 4841, April 20, 1885. 6d.

THE author claims as his invention, the arrangement by which a selenium-celled electrical circuit is connected with a separately supplied one, or series of separately supplied ones, lighting an electric lamp in such a manner that, when light or shadow falls on the selenium cell, the light of the lamp flashes out or becomes more or less extinguished, as the case may

be; and, further, the varying of the illumination by the lamp with the degree of light falling on the selenium so as to make the lamp available alike for the transmission of writings, drawings, paintings, and other gradually shaded pictures—through the medium of telegraphic wires—and for their reproduction faithfully photographed. It employs the varying current, passing through the varying lighted selenium cell, to excite the distant electro-magnet, which for the transmission of simple outlines throws on and off the current to an electric lamp—or, it may be, turns the stop-cock of a gas-jet—and for shaded pictures switches on a greater or less number of subsidiary currents to the lamp, according as more or less light falls on the selenium.—W. B.

Improvements in Galvanic Batteries. A. Schanschickl, Surrey. Eng. Pat. 5202, April 27, 1885. 4d.

To avoid local action in a galvanic battery, and to render its current constant, the author proposes to coat the positive, and in some cases the negative, plates with collodion, gelatine, or other like protective coating.—W. B.

Improvements in Galvanic Batteries. A. R. Upward and C. W. Pridham, London. Eng. Pat. 7461, June 18, 1885. 8d.

A BATTERY CELL is constructed with a zinc element immersed in a solution of chloride of zinc separated by a porous diaphragm from a carbon element around which chlorine gas circulates.

The chloride of zinc around the zinc element operating electrolytically, local action is avoided, whilst at the same time the full electromotive force due to zinc burning in free chlorine is obtained.—W. B.

Improvements in Galvanic Batteries. W. W. Popplewell, Southampton Buildings, London. From F. L. O. Lathrop, J. W. Carter, and C. Faber, New York. Eng. Pat. 1151, January 26, 1886. 8d.

THE invention consists of a metallic jar or cell, that is lined in the interior with rubber or other acid-resisting material, the said rubber lining being extended over the edge of the jar, of a porous cup provided with enlarged rounded ends and parallel sides that approach closely to each other, a zinc made in the form of a screw, with one or more threads, and provided with a depression or pocket at its top part that communicates by a hole with the screw-thread, so as to supply the mercury for amalgamating the zinc while in use and without removing it from the jar, and of carbons made in the form of plates, and provided with conical or diamond-shaped projections or teats at both sides.—W. B.

An Improved Electrode for Secondary Batteries. H. J. Allison, London. Eng. Pat. 1354, Jan. 30, 1886. 6d.

AN electrode for secondary or storage batteries having a new construction of the metal framework or retaining plate, and a new composition, which is inserted in and supported by the said plate.—W. B.

XX.—FINE CHEMICALS, ALKALOIDS, ESSENCES, AND EXTRACTS.

On the Alkaloids from Fennugreek Seeds. E. Jahns. Ber. 18, 2518–2523.

THE frequent occurrence of alkaloids in the seeds of papilionaceous plants induced the author to examine those of fennugreek (*Trigonella junium gracum*). Two alkaloids were obtained, choline, and another which the author names trigonelline. Possibly a third was also present in small quantity.

The pulverised seeds were extracted with seventy per cent. alcohol, and after evaporation the residual liquor was precipitated with lead acetate and soda. After

removal of lead from the filtrate and evaporation, the alkaloids were precipitated by potassium-bismuth iodide and sulphuric acid. The bases were only completely precipitated after some weeks, and were then converted into the mercuric iodide compounds to separate albuminous matter. The bismuth compounds were decomposed by soda; the filtrate carefully neutralised with sulphuric acid, and mercuric iodide added until no more potassium iodide remained. In this way only the choline salt was precipitated. After filtration the solution was acidified with sulphuric acid, when the trigonelline compound separated in oily drops, which rapidly solidified. By evaporation of the mother-liquor and addition of mercuric iodide, the remainder of the trigonelline compound was precipitated. The yield of choline was about 0.05 per cent., and of trigonelline, 0.13 per cent.

The free bases were separated and purified in the usual manner. The choline was identified by the formation and analysis of the platinum and gold salts. The crystalline form of the platinum double salt was also determined.

Trigonelline, $C_7H_{11}NO_2 + H_2O$, crystallises from alcohol in colourless prisms, which possess a weak saline taste. It is hygroscopic and easily soluble in water, but is insoluble in ether, chloroform, and benzene. The solutions are neutral. Potassium-bismuth iodide gives a brick-red precipitate in acid solutions, and a bulky precipitate is formed with phospho molybdic acid. Tannic acid produces a turbidity. Gold chloride and bromine water give precipitates only in concentrated solutions. Analyses of the free base, the hydrochloride and the platinum and two gold double salts were made.

Trigonelline is isomeric and probably identical with pyridine-betaïn, prepared by v. Gerichten by heating pyridine with monochloroacetic acid, the only difference being that pyridine-betaïn hydrochloride is coloured blue by sodium amalgam, and trigonelline yellow. By heating trigonelline with concentrated caustic potash, a distillate is obtained which appears to contain pyridine.—S. Y.

Synthesis of Vanillin. M. Ulrich. Ber. 18, 2571–2573.

The four metamethoxymononitrobenzaldehydes.—A method of preparation of *m*-methoxynitrobenzaldehyde, yielding three isomers, was patented by Messrs. Meister, Lucius & Brüning (Ger. Pat. 18,016) in 1881. The formation of the isomeric mononitro compounds was called in question by Tiemann (Ber. 15, 2043 and 3052; this Journal, 1883, 268–269), and later by Schnell (Ber. 17, 1381), but is confirmed by the author. Metamethoxybenzaldehyde was treated at 0° to 10° with nitric acid of specific gravity 1.46 until a drop of the mixture, rubbed with water on a watch-glass, crystallised rapidly. The product, when recrystallised from benzene, separated in three portions. Of these, the first and largest consisted of a nitrometamethoxybenzaldehyde, an ortho-derivative, as proved by its giving the indigo reaction. The crystals melt at 167°. The second small portion crystallised in needles, melting at 82–83°, and was similarly shown to be an ortho-derivative. It is named β -nitro-*m*-methoxybenzaldehyde. Lastly, compact crystals of γ -nitro-*m*-methoxybenzaldehyde, melting at 97°, were deposited. This compound formed snow-white needles, melting at 126°, when treated with acetone and caustic soda. It proved to be the meta-derivative, for the author succeeded in preparing the remaining isomer, a para compound, by a different process. Metanitrobenzaldehyde was converted into methyl-*m*-methoxybenzoate, and this was treated as above with nitric acid. The paranitro compound thus prepared crystallised from alcohol in white needles, melting at 163°. The ether was saponified with 0.5 per cent. caustic potash, and oxidised in the alkaline solution with permanganate. Paranitrometamethoxybenzaldehyde crystallised in part from the filtered solution in very fine needles, melting at 62°. The remainder was extracted with ether. This compound, when treated with acetone and caustic soda, forms a compound which crystallises in fine needles, melting at 84°. By replace-

ment of the nitro group by a hydroxyl group (Ger. Pat. 18,016) *p*-nitro-*m*-methoxybenzaldehyde is converted into vanillin.—S. Y.

Japanese Medlar. J. Peckalt. Ztschr. Oesterr. Apoth. Ver. 1886, 24, 1.

THE Japanese medlar (*Eriobotrya japonica*), a tree from 5 to 6m. high, has been transplanted from its home to Brazil with the greatest success. Its fruits are yellow, of the size of a plum, and contain from 2 to 5 blackish, brown seeds. By fermentation of the fruit, a drink can be prepared, which is exactly like the Swiss "Kirschwasser" as regards smell and taste. On distilling the crushed seeds with steam, the *aqua Eriobotryae* is obtained, which contains 0.05 per cent. of hydrocyanic acid, and cannot be distinguished from *aqua Lauracerasi*. The leaves of the medlar proved a very effective cure against chronic diarrhoea.—S. H.

Paraquinanisol. Z. H. Skraup. Monatsh. f. Chem. 6, 760—784.

78GRMS. anisidine, 50grms. nitranisol, 320grms. glycerol and 125grms. strong sulphuric acid are heated with an inverted condenser for two hours, and then with a further addition of 50grms. H_2SO_4 for two hours more. Unchanged nitranisol is distilled off by steam, and anisidine and quinanisol separated by alkali. The quinanisol is further separated from the anisidine by means of the difficult solubility of the acid sulphate of the quinanisol. Quinanisol, $C_{10}H_9NO$, boiling-point 304—305°, is a light yellow oil, turning green and then reddish violet on standing. The salts of *p*-quinanisol have a blue fluorescence in aqueous solution, and give, like quinine, with chlorine water and ammonia, a green colouration or precipitate. With Sn and HCl, quinanisol gives tetrahydroquinanisol, $C_{10}H_{13}NO$, called "thalline." The hydrochloride is freed from quinanisol by recrystallisation from alcohol and alcohol ether. With bromine, it yields a yellow substance of the formula $C_{10}H_9Br_2NO$. The salts are good antipyretics, and are said to be especially useful in cases of yellow fever. With methyl iodide, three compounds are formed: the one is basic thallinehydriodide ($C_{10}H_{13}NO$), HI, the second dimethylthallinehydriodide, $C_{10}H_{12}NO(CH_3)_2I$, and the third is methylthalline. In this process, methylthalline is a by-product; whereas with ethyl iodide, ethylthalline is the principal compound formed. It forms hygroscopic salts. The hydrochloride has the formula $C_{10}H_{12}NOC_2H_5HCl$. From thalline and benzylchloride, benzylthalline has been prepared.

—J. B. C.

Is Hopeine identical with Morphine? Chem. Zeit. 10, 207 and 238.

OWING to Williamson's publication on the new alkaloid "hopeine" and its reactions, Ladenburg repeated the experiments of the former on a preparation sold under the name of hopeine, and made by the London Concentrated Produce Company. This preparation was compared with pure morphine, special attention being given to those reactions which were stated by Williamson as being characteristic of hopeine. These could not be obtained in any case, and Ladenburg therefore concludes that morphine and hopeine are identical substances. In reply to Ladenburg, Williamson states that from what he was able to learn, the Concentrated Produce Co. has never yet prepared hopeine by his method, but from lupuline, and the difference of his results from those of Ladenburg is undoubtedly due to the fact that hopeine prepared from lupuline contains an alkaloid which is identical with morphine, but contains only traces of the true hopeine. The two investigators have now taken steps to work on a common raw material, in order to elicit the truth.—S. H.

Iodoformium Aromatisatum. Krieger. Pharm. Zeit. 1885, 30, 744.

ALTHOUGH the iodoform manufactured by E. Schering, of Berlin, by means of electrolysis, possesses a more agreeable odour than the usual kinds found in commerce, it is nevertheless sufficiently unpleasant. To disguise the smell, the author adds a few drops of the ethereal oil of sassafras wood.—J. B. C.

The Extraction of the Alkaloids from Cinchona Bark. J. E. de Vrij. Pharm. Rundsch. 1885, 3, 225.

THE author finds that the total alkaloids may be extracted with dilute HCl, HNO_3 , or H_3PO_4 ; but incompletely with H_2SO_4 . HCl is found to give the best results. The amount of acid must be in the proportion of 4 molecules to 1 molecule of the total alkaloids, for which 310 may be taken as the molecular weight. To determine the quantity of alkaloids, 20grms. of the finely-powdered bark are digested with 180—200cc. of dilute HCl, and the extract precipitated with an excess of caustic soda. The precipitate is washed upon a double filter with water until the washings are colourless. The filtrate is measured, and owing to the solubility of the alkaloids, .0585grm. is added for every 100cc. of washings. The precipitate is dried between filter-paper, then at a gentle heat, and weighed until constant.—J. B. C.

The North American Aconite. Prof. Lloyd and C. G. Lloyd. Pharm. Rundsch. 1885, 3, 231.

OF the many kinds of aconite growing in the States, two species are of interest—viz., *A. uncinatum* and *A. Fischeri* Reichenbach. *A. uncinatum* grows on the banks of the mountain streams of the Alleghanies. The stem is 6—1.5m. high. It is identical with *A. ferox* of the Himalaya Mountains; but whereas this plant is rich in aconitine, the other contains only traces. *A. Fischeri* is the only American source of aconitine for medicinal purposes. This species grows on the mountains bordering the coast at a height of from 2500—3500m. The stem is 1—1.5m. high. The root resembles *A. napellus*.

—J. B. C.

The Solubility of Mercurous Iodide in Fats and other Bodies. C. Mchu. Journ. Pharm. Chim. 885, 5 Ser. 12, 249.

SWEET almond oil dissolves mercurous iodide in sufficient quantity for most therapeutic objects at 100°. 1000grms. oil dissolve 13grms. iodide, of which two-thirds separate on cooling; at 180° 1000grms. oil dissolve 80grms. Oil which contains 4grms. iodide to 1000 does not deposit any salt on cooling, so that 4 : 1000 is a practically reliable proportion. Potassium iodide increases the solubility. 1000grms. almond oil dissolve 50grms. Hg_2I_2 . KI. Olive oil behaves like almond oil. Poppy-seed oil takes up three times the quantity of iodide. Cocoa-nut oil dissolves 13grms. per 1000. Castor oil is one of the best solvents, and dissolves 20grms. Tallow dissolves 12.5grms. at 100°. Vaseline dissolves only 2grms. at 100°. Phenol dissolves 20grms. at 100°, of which more than half separates out on cooling. 1000grms. benzene take up 4grms. in the cold.

—J. B. C.

Note on Mercury Tannate. Ch. Casthelaz. Journ. Pharm. Chim. 1885, 5 Ser. 12, 352.

THE author recommends for the preparation of mercurous tannate the precipitation of mercurous acetate with tannin, whereby a pure compound is obtained. As the mercuric acetate is much more soluble than the mercurous salt, the latter is readily obtained pure. The salt is dissolved in warm water, with the addition of glucose, to reduce any trace of mercuric salt present, and the filtered solution at 50° is poured into a cold solution containing an excess of tannin. A grey precipitate forms, which is washed, pressed and dried at a low temperature. For the preparation of mercuric tannate, a dilute solution of mercuric nitrate may be used, or mercuric

acetate, or finally a solution of mercuric acetate, obtained by boiling mercuric nitrate with sodium acetate.

—J. B. C.

A New Constituent of the Atropa Belladonna. H. Kunz. Arch. Pharm. 1885, 23, 721.

(1.) IN addition to ordinary belladonna and hyoscyamus alkaloids, bilineurin or cholin occur, which are soluble in water. (2.) In the alkaline extract of belladonna, chrysotropic acid occurs, and it is to this substance that the fluorescence is due. This acid crystallises in light yellow prisms. (3.) In addition to the above acid, leucotropic acid occurs. This crystallises from ether in silky prisms. (4.) Belladonna extract contains also 6 per cent. of succinic acid.—J. B. C.

Improvements in the Manufacture of Acetate of Amyl. W. V. Wilson, colour manufacturer, Mile End, E. Eng. Pat. 4669, April 15, 1885. 4d.

THE claim is for mixing fusel oil with acetate of lime, treating with excess of hydrochloric acid and distilling over the acetate of amyl.—T.

Obtaining Granulated Antiseptic Preparations. W. Dalrymple Borland, Highbury. Eng. Pat. 12,985, October 28, 1885. 6d.

THE patentee avails himself of the intumescence of partially dehydrated borax to produce spongy granules by heating carefully. He charges these granules with various antiseptics.—T.

XXII.—GENERAL ANALYTICAL CHEMISTRY.

Improvements in and relating to Chemical or Analytical Balances. W. E. Heys, Manchester. From E. Becker, New York. Eng. Pat. 15,678, December 21, 1885. 6d.

THE inventor claims a new device for shifting a small balance weight, or rider, placed on the graduated upper surface of the beam of an analytical balance, by means of a rod which runs parallel with the scale beam, and is carried near its middle upon the scale column, whilst one end passes through and is supported by the glass case which encloses the balance. The rod can be shifted longitudinally as well as turned on its axis, and is provided with two fingers inside the case which deal with the rider weight as required. The patent also covers an improvement in the construction of the base of the case, with the view to adding to the rigidity of the whole.—B.

Estimation of Iron and Aluminium in the Presence of much Phosphoric Acid. Chem. Zeit. 10, 120.

THIS case chiefly occurs on analysing phosphates as used for the manufacture of artificial manure. After separating silica the solution is made up to 500cc. In 50cc. the phosphoric acid is determined by the molybdic method; in another 50cc. iron is estimated by titration with permanganate, and lastly a known quantity of ferric solution is added to 50cc. of the solution in order to precipitate by ammonia the whole of the phosphoric acid as ferric phosphate. After deducting from the weight of this precipitate in the dry state the amount of iron peroxide added, the rest will represent alumina, iron peroxide and total phosphoric acid; and subtracting from it the phosphoric acid and iron peroxide, previously estimated, the difference shows the amount of alumina.

—S. B.

Analysis of Manganese. C. Meineke. Chem. Zeit. 9, 1787.

A REPLY on the subject of Hampe's method for estimation of manganese with KClO_3 . The author finds that the results obtained by this method are in some cases too low.—J. B. C.

The Determination of Iron and Aluminium in Natural Phosphates. Chem. Zeit. 9, 1752.

WITH reference to a previous communication on this subject, which appeared in the above journal (*Chem. Zeit.* 9, 1050), Dr. Lucion has added the following information:—The method which was first proposed had the advantage of being independent of the insolubility of the phosphates of iron and aluminium in acetic acid. The method is briefly as follows:—The precipitate formed with ammonia is weighed, and from this the weight of the phosphoric acid and lime is deducted. The value for the lime is the difference between the total amount of lime and that remaining in the ammoniacal liquid. The objection may be raised to this method (in determining very small quantities) that one determination is dependent on three others. If the solution of the phosphate is precipitated with ammonia, and then oxidised with acetic acid, the whole of the lime cannot be eliminated by washing, even when boiling water and acetic acid are used, lime being retained by molecular adhesion. In order to free the precipitate of iron and aluminium phosphate completely from lime, the following precautions must be taken:—

1. The precipitation should be made in a very dilute solution ($\frac{1}{2}$ l.) 11. The precipitate is redissolved in hydrochloric acid, diluted, ammonia and acetic acid added, and filtered through the same paper used in the first operation. In this way a precipitate free from lime is obtained. The next operation is simple. It is generally supposed that alumina and iron form half of the precipitate, and this is correct when iron is in excess—not, however, when alumina preponderates. The phosphoric acid may be determined in the precipitate after heating, or in an equal part of the original liquid. Alumina and iron are then obtained by difference. If the iron alone is required, it is titrated with permanganate and 71 parts phosphoric acid are calculated for 80 of iron. The remainder is phosphate of alumina, from which the alumina may be calculated, as 122 aluminium phosphate give 51 alumina.—J. B. C.

Review of Indicators used in Volumetric Analysis. G. Lunge. Ber. 18, 3290—3291.

THE number of indicators introduced recently into alkalimetry has become largely extended, and increases steadily. Certain Institutes ignore this fact and continue to employ exclusively the apparently beatified litmus solution. This appears strange, because not only is litmus very much less sensitive than other indicators, but the boiling of the solution, as required in many cases, whereby the glass vessel is attacked and alkali dissolved, causes an addition to the errors of analysis. Many indicators which are not affected by CO_2 allow of titration in a cold solution. A series of indicators and their sensitiveness has been experimented upon by R. S. Thomson (*Chem. News*, 47, 123, 135, 184; 49, 32, 38, 119; 52, 18, 29). Thomson finds methyl orange to be one of the most sensitive and useful indicators for alkalis, mineral acids, etc. The objections formed against it are, in consequence of the solution having been too concentrated or the titration made in a hot solution, and also because instead of methyl orange one of Witt's tropcolines has probably been used. Fisher and Phillip have recently recommended the use of the nonsulphonated methyl orange or dimethylanidoazobenzene. The author does not find it as sensitive as methyl orange. These results have also been confirmed by R. J. Thomson. R. Engel and J. Ville have recently called attention to two new indicators, indigo-sulphonic acid and Poirrier's cotton blue C4L. The former only indicates the change of colour slowly, and is therefore useless; the latter gives a sharp indication, but unfortunately the colour changes before the caustic alkali is neutralised.—J. B. C.

Proposed Scheme for the Detection of the Organic Colouring Matters. O. N. Witt. Chem. Ind. 9, 1—7.

THE number of artificial colouring matters used in the trade is very large, and the difficulty in distinguishing them is increased by the fact that the same colouring mat-

ter is sold under different names. The object of the present paper is to give a method for the qualitative analysis of some of the more important colouring matters. They are arranged according to the reactions which they give. Before analysing the dyestuff it is important to know whether it is a mixture or a single substance. This may be ascertained in the following way. Some of the powdered substance is spread on filter paper, and the latter is moistened on the under side with water or alcohol. The paper is stained in the case of a homogeneous substance with streaks of the same shade of colour. In other cases different shades will run side by side and may be readily detected. The difference is more readily observed in transmitted light. The approximate quantities in the mixture may also be estimated. This is, so far, of importance, as it may be necessary to distinguish actual mixtures from a colour made to a certain shade with a slight addition of another substance. In the latter case the colouring matter is practically homogeneous, and may be analysed accordingly. Among the azo-colours, mixtures of shades occur which are so similar, that the filter-paper method does not suffice for their detection. The fact that these azo-compounds dissolve in concentrated H_2SO_4 with characteristic shades may be here conveniently utilised. The powder is strewn on the surface of perfectly colourless sulphuric acid contained in a porcelain basin. The observer will see at once if the particles dissolve with the same colour. If, for example, the mixture be one of orange with croceine scarlet, carmine red streaks will form beside those of indigo blue. Mechanical mixtures occur most frequently. Sometimes mixtures are prepared by evaporating solutions of the different colouring matters. In this case the test of the dyeing power can only be employed, as the substances are too intimately associated to be detected by the above methods. This test is based upon the fact that in these mixtures one colouring matter has a greater affinity for the fibre than the others. A bath of the colour is prepared, and small silk or woollen skeins are successively dyed until the bath is exhausted. If a mixture is present the first and last skeins will possess distinct shades. For example, if the dyestuff consist of a mixture of green and violet, the wool first absorbs the violet, and leaves a green solution, which imparts all its colour to silk. Impurities in a homogeneous colour may also be detected by this method. These tests may be completed in a few minutes by using miniature apparatus. It is also important to determine the non-colouring constituents, such as common salt. The colour is in this case burnt and the chlorine determined in the ash. Amongst other adulterations, the following may be mentioned:—

1. *Sugar*.—On account of its high price this substance is not largely used. Sugar is occasionally coloured with magenta and mixed with that colour. Its crystalline form, taste, and the fact that the powdered crystal is white, afford ready means of detection.

2. *Dextrin* is easily recognised by its smell on dissolving the colour in boiling water. It is mostly used with rosaniline colours. The colouring matter may also be separated with alcohol, which leaves the dextrin undissolved. The dextrin may be determined quantitatively in this way.

3. *Common Salt* is exceptionally used for diluting cheap and soluble colours, as, for example, Bismarck brown. Alcoholic extraction of the colouring matter may be here employed.

4. *Glauber's Salt* is *par excellence* the diluent for all azo-colours. Its detection may be effected by dissolving the colour in water, precipitating with an excess of pure sodium chloride, filtering off from the precipitate, and testing the sulphuric acid in the filtrate. This method gives approximately quantitative results. To obtain exact quantities, the precipitate with sodium chloride must be washed on the filter with solution of common salt until free from H_2SO_4 .

5. *Magnesium Sulphate* is occasionally employed in place of the above, and may be detected by a similar method.

It is sometimes of interest to the dyer, and especially to the printer, to know, in the case of a basic

colour, with which acid it is combined. In most cases it is the hydrochloride, but exceptions are not unfrequent. The base is precipitated with ammonia, and the acid tested for in the filtrate. In some cases, as, e.g., safranin, this method cannot be employed. The test must then be effected in the solution of the colour itself. Double zinc chloride salts leave an ash on heating, which may be tested for zinc. As in the case of a basic colour, the acid is tested for, so, in that of an acid colouring matter, the base may be detected. The substance is dissolved in water, the acid precipitated with pure concentrated HCl ; the base is found in the filtrate. In the case of ammonia, it suffices to warm the substance with caustic soda. The colouring matters in the following list are grouped according to the shade which they impart to woollen fibre. A preliminary test must in every case be made, and according to the result the colour will come under one of the groups.

Apparatus and Reagents for Analysis.

In addition to a large test tube, which may be used as a colour bath, the following will be found useful:—

1. A number of clear white porcelain basins or watch glasses placed on a white surface.
2. A number of good test tubes.
3. Funnels and filter papers.
4. A lamp.
5. A pocket spectroscope which gives the Fraunhofer lines distinctly.
6. A pocket microscope.

The following reagents:—Distilled water, pure colourless sulphuric acid, hydrochloric acid, ammonia, zinc dust, and the usual qualitative reagents.

A.—RED COLOURS.

I. *The colour is insoluble in cold and hot water, easily soluble in alcohol.*

a. The alcoholic solution is salmon-red, without fluorescence. The solution in concentrated H_2SO_4 is red violet.—*Carminaphtha*.

b. This colour, not widely known, is manufactured by Durand and Huguenin, of Basel, and finds a limited application in calico printing. The alcoholic solution is bluish-red and gives an intense orange-red fluorescence. It gives a broad absorption band with the spectroscope, which extinguishes the yellow and the green. The solution in concentrated H_2SO_4 is green-grey. On diluting with water it is coloured red, and a violet-red precipitate forms.—*Magdala Red*.

c. Insoluble in cold water, soluble in hot. Its behaviour in alcoholic solution is similar to that of Magdala red, but it gives an absorption band lying more to the right, so that a portion of the yellow is visible. The solution in concentrated H_2SO_4 is colourless; on diluting, each drop of water produces a red tint, which disappears on shaking, until the dilution reaches a certain point, when the liquid becomes of a magenta tint.—*Quinoline Red*.

d. The alcoholic solution is fluorescent, but the fluorescence is greener. The solution in sulphuric acid is lemon yellow to orange, and does not give on dilution any characteristic change of colour.—*Spirit Eosine*.

e. The alcoholic solution is a dusky bluish-red. The solution in H_2SO_4 is green, on dilution blue-red.—*Rhodindine* (induline of the naphthalene series).

II. *The colour is more or less soluble in cold water, readily in boiling water.*

a. *Basic Colours* (precipitated with caustic soda).

a. The aqueous solution is blue-red; on the addition of HCl or H_2SO_4 it becomes yellowish-brown. Sodium acetate reproduces the red colour. In a dilute solution, which is faint red, on the addition of ammonia, wool is coloured an intense red. Zinc dust decolorises the aqueous solution, and the colour cannot be restored. The solid product consists either of distinct green crystals, or a metallic green powder which dissolves in H_2SO_4 with a yellow-brown colour.—*Fuchsin* (rubin, magenta, aniline red).

b. Blue red solution. Ammonia forms a flocculent orange precipitate, extractible by ether, giving a yellow fluorescence. Solution in concentrated H_2SO_4 green, on dilution changing from blue and violet to red.—*Toluylene Red* (neutral red, generally very impure; the reactions, therefore, are not distinct).

β. Acid Colours or Basic Colours of the Saffranine Group (not precipitated with caustic soda).

a. On addition of NaOH to the aqueous solution a change of colour is produced; the liquid is coloured blue. Solution in H_2SO_4 brownish-yellow, on dilution turning redder.—*Galleine*.

b. The aqueous solution gives, on addition of alcohol, a distinct grey-yellow fluorescence. Addition of acid produces no precipitate. Zinc dust decolourises, but in presence of air the original colour is restored. Solution in H_2SO_4 green, on dilution changing to blue and then to red.—*Saffranine* and *Saffranisol* (identified by the shade on dyeing).

c. The aqueous solution is a pure red, and gives a greenish-yellow fluorescence, which is more pronounced on dilution. The addition of acid gives a yellow flocculent precipitate, soluble in ether. The ethereal solution is pure yellow, without fluorescence. Solution in H_2SO_4 yellow.—*Eosin*.

d. The aqueous solution is of a bluer red, and gives no fluorescence. Acids give a straw-yellow precipitate, which dissolves in ether with the same colour. Solution in H_2SO_4 golden yellow. Zinc dust in the ammoniacal solution decolourises. When this solution is dropped on to filter paper it is immediately coloured intense blue-red. (Distinction from Eosin).—*Eosin Scarlet* (bromo-nitro fluorescein).

e. Solution blue-red without fluorescence. Acids give a yellow precipitate, soluble in ether. Solution in H_2SO_4 orange-yellow. Zinc dust and ammonia decolourise, and the solution becomes in air only very faintly coloured.—*Phloxin*, *Rose Bengal* (distinguished by difference in shade).

f. The concentrated hot aqueous solution solidifies to a jelly on cooling. Acids produce a brown, flocculent precipitate. On warming with zinc dust and ammonia, the solution changes to yellow, and eventually becomes colourless. The solution in H_2SO_4 is grass-green. On dilution it changes to blue, and then a dirty brown precipitate forms.—*Biebrich Scarlet* (double scarlet).

g. Barium chloride added to the aqueous solution gives a flocculent red precipitate, which, on boiling, becomes crystalline, and simultaneously dark violet. Solution in H_2SO_4 is indigo blue, changing on dilution to violet and red.—*Croceine Scarlet*, *βB*.

h. The aqueous solution, with the slightest trace of acid, is coloured pure blue. It colours cotton in aqueous solution fast red. Solution in H_2SO_4 slate blue, not changing on dilution.—*Congo Red*.

i. The aqueous solution solidifies on cooling with the separation of brilliant bronze-coloured crystals. Solution in H_2SO_4 violet, on dilution a brown precipitate forms.—*Xylidine Ponceau* (from α-naphthol sulphonic acid, D.P. 26,012).

j. Magnesium sulphate, added to the concentrated aqueous solution, forms, on cooling, long silky needles of the magnesium salt. Solution in H_2SO_4 violet. Wool is dyed bright scarlet.—*Croceine Scarlet*, *βB extra* (from diazo-naphthionie acid and croceine-β-naphthol-sulphonic acid).

k. The aqueous solution produces, on addition of calcium chloride and barium chloride, an amorphous flocculent precipitate. Solution in H_2SO_4 is rose or carmine, forming, on dilution, a brown red precipitate.

Colouring matters from β-naphthol disulphonic acid are distinguishable by their different shades on dyeing.—*Ponceau R*, *2R*, *3R*, *Anisol Red* *Coccine* (D.P. 32291).

l. Wool is dyed magenta. In the aqueous solution, calcium chloride produces a red semi-crystalline precipitate. Solution in H_2SO_4 blue-violet, changing on dilution to red.—*Acid-azorubin* (D.P. 26,012).

m. A deep brownish-red solution, which dyes wool the same colour. The solution in H_2SO_4 blue, on dilution a yellowish-brown precipitate is formed.

The concentrated boiling aqueous solution gives, on the addition of a drop of saturated solution of soda, a crystalline precipitate of the sodium salt in the form of brown scales.—*Fast Red* (*Rocellin*).

n. Aqueous solution, Bordeaux red. A flocculent amorphous precipitate with calcium and barium chloride. Solution in H_2SO_4 indigo blue.—*Bordeaux B*, (D.P. 3229).

o. Aqueous solution, blue red, which is decolourised with NaOH. Acetic acid restores the original colour.—*Acid Magenta*.

B.—YELLOW AND ORANGE COLOURS.

I. The colour is insoluble in cold water, nearly or quite insoluble in hot water, soluble in alcohol.

a. Solution in lemon yellow, alkalis and acids produce a slightly deeper tint.—*Phthalogluconine*.

b. The solution is golden yellow. Acids produce not change. Alkalis and boric acid change the colour to a deep reddish brown.—*Turmeric*.

c. The solution is golden yellow. The addition of HCl produces a red colouration. Amyl nitrite has no action on boiling.—*Dimethylglutidazobenzene*.

d. Same as for *c*, but amyl nitrite decolourises and produces an evolution of nitrogen.—*Amidazobenzene*.

II. The colour soluble in cold, very soluble in hot water. Soluble in conc. H_2SO_4 without a deep colouration.

a. Caustic soda produces no precipitation.—*Acid Colours*.

a. A greenish yellow solution with a bitter taste. Alkalis change it to dark yellow. Acids have no action.—*Picric Acid*.

b. Golden yellow solution. Acids produce a white precipitate.—*Martius Yellow*.

c. Golden yellow solution, not precipitated by acids. KCl produces crystallisation in fine needles.—*Acid Naphthol Yellow*.

d. The solution is brown yellow, and has a green fluorescence, which disappears with acids, a precipitate being at the same time formed.—*Fluorescein* (Uranine) *Benzylfluorescein* (Chrysolin).

In order to distinguish these two colours, a more exact investigation of the separated acids is necessary.

e. Solution is golden yellow, not precipitated by acids. It is not decolourised by zinc dust and ammonia, or tin salt and HCl.—*Quinoline Yellow*.

β. Caustic soda produces a precipitate.—*Basic Colours*.

a. Yellow precipitate with alkalis, soluble in ether, with a yellow colour and green fluorescence.—*Phosphine*.

b. Milk-white precipitate with alkalis, soluble in ether to a colourless solution, with a greenish blue fluorescence.—*Flavraniline*.

c. Milk-white precipitate with alkalis, soluble without colouration, and without fluorescence in ether. The yellow solution boiled with HCl is gradually decolourised.—*Auramine*.

III. The colour is soluble in water. The H_2SO_4 solution is strongly coloured.—*Azo Colours*.

a. Caustic soda produces no precipitate.

a. The colour on wool is yellow. The aqueous solution solidifies, on cooling, to a blood-red jelly. Solution in H_2SO_4 brownish yellow.—*Chrysoidine*.

b. The colour on wool is orange brown. The solution does not gelatinise on cooling. Solution in H_2SO_4 brown.—*Icesuvin* (Bismark brown, Phenylene brown).

β. Caustic soda produces no precipitate.

a. Solution in H_2SO_4 yellow; on dilution, salmon red. Solution in water yellow.—*Fast Yellow*.

b. Solution in H_2SO_4 yellow; on dilution, carmine red. Solution in water, yellow, which crystallises on

cooling in golden plates. Dilute acids produce a reddish violet precipitate.—*Methyl Orange*, *Ethyl Orange*.

c. Solution in H_2SO_4 violet; on dilution, red violet, with the simultaneous formation of a steel-grey precipitate. Solution in water, yellow, which on cooling crystallises. Chloride of calcium and barium form insoluble precipitates.—*Tropaeolin OO*, *Diphenylamine Yellow*.

d. Solution in H_2SO_4 bluish green; on dilution, violet, with formation of a steel-blue precipitate. Solution in water, yellow, and crystallises on cooling. Barium chloride forms a yellow salt, which crystallises from a large quantity of water in plates.—*Yellow N* (Poirrier).

e. Solution in H_2SO_4 yellowish green; on dilution, violet, with a grey precipitate. Solution in water, yellow, crystallising on cooling. Calcium chloride produces an orange precipitate, which on boiling changes to red, and becomes crystalline.—*Leucoline*.

f. Solution in H_2SO_4 carmine red; on dilution, yellow. Solution in water, yellow; often cloudy; turning red to violet with alcoholic caustic soda.—*Citronine* (Indian yellow, Curcumin).

g. Solution in H_2SO_4 deep orange; no change on dilution. Aqueous solution, orange; on addition of calcium chloride crystalline calcium salt.—*Orange G* (D.P. 3229).

h. Solution in H_2SO_4 brown-orange; no change on dilution. Aqueous solution, yellow. Addition of little HCl produces crystallisation in yellow plates; addition of much HCl separates the free acid in grey needles.—*Tropaeolin O* (Chrysoin).

i. Solution in H_2SO_4 carmine red; on dilution, orange. Aqueous solution, reddish orange. Calcium chloride precipitates the red calcium salt, which crystallises from boiling water, in needles.—*Orange II*. (β -naphthol-orange mandarine).

j. Solution in H_2SO_4 violet; on dilution, orange. Solution in water red-orange, which, on the addition of NaOH , changes to carmine-red.—*Tropaeolin OOO* (Orange I).

C.—GREEN COLOURS.

a. Slightly soluble in water, with an olive brown colour. Alkalis effect complete solution with a grass-green colour. H_2SO_4 solution, dirty-brown.—*Caraleine*.

b. Readily soluble in water, with a green colour. Alkalis produce a rose-coloured or grey precipitate. Strong acids, a yellow colouration.—*Victoria Green*, *Brilliant Green* (may be distinguished by their different shades on dyeing).

c. Readily soluble in water, with a bluish-green colour. Acids colour it yellow; alkalis decolourise the solution without precipitation. A coloured sample is turned violet above 100° .—*Iodine* and *Methyl Green*.

d. Readily soluble in water, with a faint-green colouration. Acids increase the intensity; by a further addition the yellow colour is produced. Alkalis decolourise completely. Silk and bleached wool can only be dyed in an acid bath. (Methyl green also in a neutral bath.) Dyed samples may be heated to 150° without change.—*Sulphonic Acids of Benzaldehyde Green* (acid green, Heiveta green, and light-green S).

D.—BLUE COLOURS.

a. Insoluble in water. The alcoholic solution is coloured blue of different shades. HCl does not modify the colour, but precipitates microscopic green crystals. NaOH produces a brownish-red colouration. Conc. H_2SO_4 dissolves it with a light reddish-brown colour.—*Rosanine* and *Diphenylamine Blue* (distinguishable by the dyed silk samples, better by gas-light).

b. Insoluble in water; the alcoholic solution is coloured red with HCl . Alkalis have no action.—*Indophenol*.

c. Readily soluble in water. HCl produces a green, NaOH a violet-red precipitate. Zinc-dust decolourises. The colour is restored by the action of the air. It contains zinc.—*Methylene Blue*.

d. Soluble in water. Acids colour it yellowish-brown. Alkalis produce a reddish-brown precipitate.—*Victoria Blue*.

e. Easily soluble in water. Alkalis produce decolourisation. Wool absorbs the colouring matter from the alkaline solution, and is coloured deep-blue on immersion in dilute acids.—*Alkali Blue*, *R-6B* (distinguished by their shades).

f. Easily soluble in water; dyes only in an acid-bath. Zinc-dust and ammonia form a colourless dye bath, as in the case of indigo. Dilute nitric acid, on boiling, destroys the colour.—*Indigoearmine*.

g. Insoluble in water; soluble in alcohol. Alkalis colour the alcoholic solution, brown-red to violet. Conc. H_2SO_4 forms a blue solution. *Induline*, *R-6B* (the solubility increases with the redness of the shade).

h. Soluble in water. Acids produce a blue precipitation; alkalis a red to violet colouration. Zinc dust and ammonia produce a colourless dye-bath; dilute nitric acid, on warming, does not decolourise.—*Soluble Indulines* (distinguished by their shades).

i. The commercial product is a grey paste. NaOH produces, in presence of air, an immediate blue colour.—*Leucoindophenol*.

j. The commercial product is a grey paste, which dissolves in NaOH without a blue colouration. The addition of grape sugar and (on warming) indigo-blue, separates in crystals.—*o-Nitrophenylpropiolic Acid*.

E.—VIOLET COLOURS.

a. Scarcely soluble in water; soluble in alcohol. The solution in H_2SO_4 has a cinnamon-brown colour.—*Diphenylrosaniline* (regina purple).

b. Soluble in water. Alkalis give a precipitate, HCl colours the solution first green, then yellow.—*Methyl Violet*, *R-6B*, *Hofmann's Violet* (distinguished by their shades).

c. Not very soluble in water. Alkalis produce a violet precipitate. Conc. H_2SO_4 dissolves it with a grey colour. On dilution the solution changes successively to grey-green, light-blue, bluish-violet, and lastly reddish-violet.—*Mauveine* (Perkin's violet).

d. Soluble in water. Acids precipitate a blue, alkalis a reddish-violet substance. With zinc-dust in acid and in ammoniacal solutions, it forms a reduced dye-bath. Solution in conc. H_2SO_4 emerald-green; on dilution, light-blue.—*Lanth's Violet* (thionin).

e. Soluble in boiling water. HCl colours it pure carmine. Conc. H_2SO_4 produces a blue; on dilution, a red colour.—*Gallocyanine*.

f. Soluble in water, with a reddish-violet colour. On addition of alcohol it gives a carmine-red fluorescence. Conc. H_2SO_4 dissolves it with an emerald-green colour. On dilution the liquid becomes blue or violet.—*Amethyst*, *Fuchsine*, *Girofle* (violet safranin colours, with ethylated nitrogen and methylated homologues of phenosafranin).

Those colours which are omitted in the above list will be considered by the author in a future paper.—J. B. C.

Characteristic Reaction of Vanillin. F. Tiemann. Ber. 18, 3493—3496.

It is known that aqueous solutions of vanillin assume a bluish violet colouration with ferric chloride. It is here shown that on heating the solution, *dehydrodivanillin*, $\text{C}_{12}\text{H}_4(\text{OH})_2(\text{COH})_2(\text{OCH}_3)_2$, separates from the liquid in fine white needles sparingly soluble in water, alcohol, ether, benzene and chloroform, but readily soluble in alkalis. The pure substance melts at $303\text{--}304^\circ$, and is derived from two molecules of vanillin by the abstraction of two atoms of hydrogen. Its formation is analogous to that of dihydymol from thymol, cedriret from ethyldimethylpyrogallol ether, and of indigo from indoxyl by means of the same reaction. When dehydrodivanillin is heated with sodium methylate and methyl iodide,

dimethyldehydrodivanillin, $C_{12}H_4(CO)_2(OCH_3)_4$, is obtained. It crystallises in white needles melting at $137-138^\circ$, is insoluble in water and alkalis, but more soluble than dehydrodivanillin in alcohol and ether. When dehydrodivanillin is fused with caustic potash it is converted into *dehydrodiprotocatechuic acid* $C_{12}H_4(OH)_4(COOH)_2$. After fusion the melt is dissolved in water, and the acid liberated by the addition of hydrochloric acid. It is purified by conversion into the calcium salt, which is subsequently decomposed by hydrochloric acid. An amorphous flocculent precipitate is obtained, which on drying melts at above 300° . This compound is slightly soluble in water, and more soluble in alcohol. With ferric chloride it gives the characteristic colour reactions of protocatechuic acid, with copper sulphate a brownish red, with silver nitrate a brown, with lead acetate a white, and with zinc sulphate a white precipitate. The salts of the alkalis and alkaline earths with this acid are soluble in water. The author concludes from these observations, and especially from the formation of dehydrodiprotocatechuic acid, that the compounds described by him are probably derivatives of diphenyl.—D. B.

Monthly Patent List.

I.—GENERAL PLANT, APPARATUS, AND MACHINERY.

APPLICATIONS.

- 4012 O. Klauwig, Halifax. Improvements in apparatus for steaming and drying solutions and other substances. Complete specification. March 23
- 4015 O. H. Castle, London. Improvements in machines for manufacturing ice. Complete specification. March 23
- 4017 A. B. Frenzel, London. Improvements in vacuum pans. Complete specification. March 23
- 4096 J. Laidlaw and A. J. Liversedge, Glasgow. Improvements in the construction of centrifugal machines, otherwise known as hydro-extractors. Complete specification. March 24
- 4159 J. R. Alsing, London. An improved triturating cylinder. Complete specification. March 24
- 4161 A. Laing, London. Apparatus for ventilating stoke holes and supplying boiler fires with heated air. Complete specification. March 24
- 4217 B. H. Thwaite, Liverpool. An improved gas generator and boiler furnace. March 26
- 4267 J. Lockhart, Sheffield. Improvements in heating apparatus. March 26
- 4314 A. H. Smith, London. An improved injector for steam boiler and other furnaces. March 27
- 4422 W. A. Entwistle and P. Smith, Manchester. Improvements in lubricating and protecting from injury the leathers of all kinds which surround the rams of all kinds of hydraulic presses, accumulators, pumps, and all other machinery where leathers of all kinds are subjected to pressure or friction. March 30
- 4429 L. A. Groth, London—Communicated by A. Traub, France. A new or improved auxiliary heater for boilers, furnaces, etc. March 30
- 4430 L. A. Groth, London—Communicated by A. E. Barthel, United States. A new or improved furnace grate. Complete specification. March 30
- 4497 T. W. Beverley, Sheffield. Improvements in blowing apparatus. March 31
- 4518 M. Reuland, London. Improvements in drying apparatus. March 31
- 4601 B. D. Healey, Liverpool. Improvements in gas-fired furnaces for various purposes. April 2
- 4609 T. G. Hardie, Burnley. The combustion and destruction of town refuse and other matter, also as a crematory,—a special form of furnace. April 2
- 4656 J. S. Sawrey, London. Improvements in filters. Complete specification. April 2
- 4700 E. N. Henwood, London. Improvements in the construction and arrangement of furnaces and appliances therefor, where hydrocarbon oil in conjunction with compressed air or steam are used as fuel. April 3
- 4736 H. E. Newton, London—Communicated by M. Hanmore, R. Van Selons Mattison, and H. G. Keasbey, United States. An improved non-conducting covering and composition for pipes or tubes and other vessels or receptacles. Complete specification. April 5
- 4773 G. Fry, London. Improved apparatus for preventing the bulging of linings of boilers or other vessels employed in oiling under pressure. April 6
- 4869 D. Hancock, D. C. Hancock, and A. H. Hancock, Stratford. Improvements in the construction of valves for hot and cold water and other fluids. April 7
- 4871 G. F. Redfern, London—Communicated by M. H. Simonet, France. An improved grinding and triturating

- 4991 A. J. Bell, Manchester. Improvements in filters. April 10
- 5032 A. M. Clark, London—Communicated by H. F. L. Worms de Romilly, France. An improved method of and apparatus for raising and forcing liquids, exhausting air and gases, blowing, boiler feeding, and other purposes. April 10
- 5251 C. E. Davis, London. Improvements in apparatus for mixing liquids. April 15
- 5292 C. Brader, Manchester. An improved covering for steam or hot water pipes, cylinders and boilers, and improved apparatus for preparing the same. Complete specification. April 16
- 5325 C. Wickstead, London. Improvements in tubes applicable to boilers, condensers, and the like. April 16
- 5310 J. R. Alsing, London. Improvements in the construction of triturating cylinders. Complete specification. April 16
- 5313 C. E. Gittens, London. Improvements in filters. April 16

COMPLETE SPECIFICATIONS ACCEPTED.

1885.

- 4889 F. Maxwell-Lyte. Crucibles, muffles, and other refractory apparatus. April 20
- 6066 W. Weldon—Communicated by A. R. Peehiney et Cie. Apparatus for cooling gases and vapours. April 2
- 6173 H. H. Lake—Communicated by E. Friedrich. Improvements in engines or boilers in which steam or a mixture of steam and hydrocarbon vapours is employed. March 26
- 6676 W. S. Boulton. Apparatus for "washing" or separating. March 26
- 7012 J. Engelson. Steam generators. April 2
- 7194 B. J. B. Mills—Communicated by C. Diener and C. A. Mayrhofer. Electro-hydraulic vacuum apparatus. April 16
- 7237 J. Imray—Communicated by La Compagnie de Five-Lille. Continuously acting centrifugal apparatus. April 16
- 7618 S. H. Johnson and C. C. Hutchinson. Improvements in filter presses. April 9
- 7677 H. Thompson. Furnaces for steam boilers and other purposes. April 6
- 7964 H. H. Lake—Communicated by F. J. Oakes. Evaporating apparatus. April 2
- 8031 H. Caswell. Improvements in and relating to furnaces. April 20

1886.

- 2168 G. Behrens. Filtering apparatus. March 26
- 2182 F. Grosvenor. Filters or water purifiers. March 26
- 2330 H. Davey. An improvement in steam generators. April 2
- 3190 J. B. Alliot and G. P. Houghton. Improvements in centrifugal drying machines. April 6
- 3559 H. E. Newton—Communicated by A. Chesebrough. Improvements in hot-air furnaces.

II.—FUEL, GAS, AND LIGHT.

APPLICATIONS.

- 4016 W. P. Thompson, Liverpool—Communicated by A. J. Ambler, United States. Improvements in apparatus for the production and utilisation of vapour fuel. Complete specification. March 23
- 4099 A. Dempster, Elland. A new or improved apparatus for purifying and enriching coal gas. Complete specification. March 24
- 4135 F. Mörth, London. Improvements in means or apparatus for supplying liquid or gaseous fuel to furnaces or fireplaces. March 24
- 4137 T. F. Veasey, London. Utilising waste heat given off from chimneys or furnaces. March 24
- 4163 A. Thomas, West Cowes. Regulating the flow of gas tar to be used as fuel in gas and other works, to be called "Tar fire regulator." March 25
- 4181 C. Holy, London. Improvements in circular or round burners for burning petroleum or similar fluids. Complete specification. March 25
- 4206 E. Brook, London. Improvements in apparatus for making gas. March 25
- 4220 M. P. Watt Boulton, London. Improvements in the application of heat to generating and heating steam. March 25
- 4250 T. Toward, W. Toward, and J. Meek, Newcastle-on-Tyne. Improvements in the production of forced draught and its application to steam-boiler and other furnaces for burning small coal and coal dust. March 26
- 4319 W. von Ruckteschell, London. A new combustible compound. December 16, 1885; previously included in No. 15175 of 1885.
- 4451 G. King, Becton. Improvements in fastenings for retort lids. March 30
- 4469 B. Loomis, London. Improvements in processes of and apparatus for manufacturing gas. Complete specification. March 30

The dates given are the dates of the Official Journals in which acceptances of the Complete Specifications are advertised. Specifications thus advertised are open to inspection at the Patent Office immediately and to opposition within two months of the said dates.

- 1498 K. Proctor and F. C. Bell, London. An improved means of and apparatus for hermetically sealing the mouth-pieces, doors, covers, and lids of gas retorts. March 31
- 1582 W. A. Barlow, London—Communicated by J. F. W. A. Jahnke, Germany. Improvements in lamps and lanterns for burning carburetted coal gas. April 1
- 1614 C. C. Marley, Middlesbrough. Improvement in marine boilers by utilising heated gases hitherto wasted. April 2
- 1617 J. Dillamore, London. A new or improved apparatus for removing tar from the hydraulic mains used in the manufacture of coal gas. April 2
- 1711 W. Hibbert, Barnsley. Reflecting gas light and heat radiator. April 5
- 1769 J. Laycock and J. Baldwin, Keighley. Steam tar injector and tar burner. April 6
- 1785 R. Hutchinson, London. Improved apparatus for the application of the thermodynamic energy of petroleum and similar combustible fluids to the propulsion of locomotives, tram-cars, torpedo and other boats or vessels, and to the driving of stationary, portable, and other engines. April 6
- 5021 H. H. Lake, London—Communicated by L. Cline, United States. An improved artificial fuel. Complete specification. April 10
- 5118 H. Johnson, Dudley. Improvements in application of gas. April 13
- 5207 H. Bumby and N. L. Wieputte, Liverpool. Improvements in or relating to the utilisation of coke dust or refuse. April 14
- 5311 J. A. Drake, Halifax. An improved construction of apparatus employed for heating gas retorts. April 16
- 5348 W. W. Box, Westminster. Improvements in gas retort lids and fastenings. April 16
- 5412 H. Hawkins, Westminster. Improvements in gas retort lids, cross bars, and appliances for tightening the said lids. April 19

COMPLETE SPECIFICATIONS ACCEPTED.

1885.

- 1023 C. J. Ball. Expanding gases and vapourising fluids by direct intermixture and molecular contact with heated gases. March 30
- 6059 J. McNair. Furnaces of retort chambers used in gas manufacture, and means for supplying heated air thereto. March 30
- 6257 C. D. Abel—Communicated by F. A. M. Alavoine. Hydraulic mains for gas-works. March 30
- 6931 A. Gontard. Purification of air or gases from solid or gaseous impurities, and apparatus therefor. March 30
- 6971 N. Frere—Communicated by A. Eln and E. Courcelles. System of heating by electricity. April 13
- 7212 G. G. M. Hardingham—Communicated by J. Grouvelle. Means for distributing heat by radiation. March 26
- 7358 A. M. Chambers and T. Smith. Improvements in coke ovens, and in methods and apparatus for collecting the products of combustion therefrom. April 20
- 7701 J. Y. Johnson—Communicated by C. Goublier. Manufacture of candles. April 6
- 7791 S. Butler. Apparatus for mixing and heating materials for manufacture of patent fuel. April 9
- 7805 J. Platt. Means for heating the air supply to furnaces for metallurgical and other purposes. April 20
- 8178 E. Green. Fuel economisers. April 20
- 9650 H. E. H. Wallis and H. T. Ratcliffe. Carburetted apparatus for burning coal gas with hydrocarbons. April 13
- 15286 C. A. von Welsbach. An illuminant appliance for gas and other burners. March 30
- 16080 E. Johnson. Improvements in open grates and stoves for saving of fuel and consumption of smoke. March 30

1886.

- 2950 J. Parkes. Apparatus for enriching illuminating gas. April 13

III.—DESTRUCTIVE DISTILLATION, TAR PRODUCTS, ETC.

APPLICATIONS.

- 4094 W. M. Fraser, Glasgow. Improvements in apparatus and arrangements for distilling mineral oils. Complete specification. March 24
- 1713 J. C. Mewburn, London—Communicated by La Société A. Renard et Duron, France. A process of and apparatus for treating colophony and other resinous substances to obtain benzene, toluene, xylene, and other products. April 5

IV.—COLOURING MATTERS AND DYES.

APPLICATIONS.

- 1387 H. H. Lake, London—Communicated by A. Leonhardt & Co., through Wirth & Co., Germany. Improvements in and relating to the manufacture of colouring matters. March 29
- 1687 T. Maxwell and J. Young, Glasgow. Improvements in the manufacture of colouring matter. April 3
- 1711 J. C. Mewburn, London—Communicated by La Société A. Collincau et Cie., France. The production of black, violet,

and other dyes or colours by means of benzyaniline or its homologues, and the application thereof to vegetable and animal materials. April 5

3333 G. Epstein, London. Improvement in obtaining albumen and colour or dye.

COMPLETE SPECIFICATION ACCEPTED.

1885.

- 9214 M. Hoffmann and A. Weinberg. Production of new azo-colours. April 16

V.—TEXTILES: COTTON, WOOL, SILK, ETC.

APPLICATIONS.

- 4174 N. M. Bateson, London. An improved apparatus for ascertaining the percentage of sand or other foreign substances in raw cotton and other fibre. March 25
- 1323 B. Fiegel, London. An improved isolation process for the preparation of fibrous spun or woven material of all kinds. Complete specification. March 27
- 1471 H. H. Lake, London—Communicated by J. T. Waring, United States. Improvements relating to the preparation of animal fibres for felting. Complete specification. March 30
- 1780 E. Tweedy, H. L. Brevoort, and J. L. Roberts, London. Improved processes for preparing fur for felting. Complete specification. April 6
- 1781 E. Tweedy, H. L. Brevoort, and J. L. Roberts, London. Improved processes for preparing fur for felting. Complete specification. April 6
- 5111 H. Brummer, London. A new or improved fibrous material, and methods for manufacturing the same. April 19

VI.—DYEING, CALICO PRINTING, PAPER STAINING, AND BLEACHING.

APPLICATIONS.

- 1389 J. Y. Johnson, London—Communicated by N. Lecomte, France. Improvements in dyeing and bleaching cotton or other fibrous materials, and in apparatus connected therewith. March 29
- 1839 W. Birch, Manchester. Improvements in apparatus for washing, soaping, dyeing, and dunging woven fabrics. April 7
- 5113 M. Oldroyd and J. W. Hepworth, Halifax. Improvements in "Oldroyd's" burl dyeing machines. Complete specification. April 13

COMPLETE SPECIFICATION ACCEPTED.

1885.

- 7187 J. C. Mewburn—Communicated by G. Lombard et Cie. Purifying, bleaching, dyeing, etc., yarns or threads. March 30

VII.—ACIDS, ALKALIS, AND SALTS.

APPLICATIONS.

- 1070 E. Arthur and E. M. Arthur, London. An improved process for obtaining crystallised sulphate of calcium. March 23
- 1388 T. Capper, London—Communicated by S. Pick, Austria. Improvements in apparatus used in the manufacture of ammonia soda. March 29
- 4737 G. J. C. M. Baron de Liebhafner, London. New caustic powders for the removal of paint and other deposits. April 5
- 1712 H. L. Pattinson, jun., London. Treating tersulphides or polysulphides of barium and strontium so as to recover the barium and strontium and obtain other products. April 5
- 1922 C. F. Claus, South Wimbledon. Improvements in the manufacture of carbonate of soda and of carbonate of potash, and in the treatment of residual products obtained in such manufacture. April 8
- 5016 J. H. Johnson, London—Communicated by J. L. Kessler, France. Improved process or means for expelling sulphuric acid in excess from sulphates and bisulphates. April 10
- 5031 N. B. Fowler, London. An improved process of treating phosphatic earths and rocks. April 10
- 5170 J. Mactear, Glasgow. Improvements in the manufacture of hydrates of strontia and of baryta. Complete specification. April 14
- 5255 A. Chantreux and I. Farinaux, Liverpool. A new or improved apparatus applicable for use in causticising alkaline lyes, dissolving chloride of lime, and the like. April 15
- 5326 T. Twynam, London. Improvements in the production of alkaline carbonates and hydrates. April 16

COMPLETE SPECIFICATIONS ACCEPTED.

1885.

- 5388 H. B. Condy. Manufacture of hyposulphates and sulphates of alkalis. March 30

6866 T. Twynam. Production of soluble phosphates of the alkalis in the manufacture of steel and iron. April 6
 6867 T. Twynam. Production of alkaline phosphates in the manufacture of iron or steel from phosphoric pig iron. April 2
 7136 E. F. Trachsell. Producing hydrate or carbonate of strontium or of barium. April 9

1886.

1861 G. H. Nichols, W. H. Nichols, and J. B. F. Herreshoff. An improved sulphuric acid tower. March 26
 2233 M. R. Pryor and A. C. Jamieson. Extraction of nitrate of soda and other salts. March 30

VIII.—GLASS, POTTERY, AND EARTHENWARE.

APPLICATIONS.

4282 T. Ide, London. Improvements in moulds for bending plate and sheet glass. March 26
 1325 H. Norris, London. Colouring glass, porcelain, china, and other like substances to imitate stained glass, and for mounting same or not with leaden, metal, wood, or paper borders for decorative purposes, intended to be called "Acme vitre." March 27
 4509 J. G. Sowerby, London. An improvement in the fire polishing of glassware. March 31
 1887 S. G. L. Giles and W. J. Petrie, London. Improvements in the method of decorating Lincrusta-Walton, Tynecastle tapestry, calicorium, and other similar embossed materials employed for the decoration of walls and other surfaces. April 7
 5157 J. Laur, London; and W. Walker, Liverpool. Improvements in the ornamenting of glass, and applying it to the covering of walls, ceilings, and other architectural purposes. April 11
 5213 W. B. Fitch, London. Improvements in the manufacture of glass bottles, and apparatus therefor. April 11
 5291 D. Rylands and H. Lindsay-Bucknall, Barnsley. Improvements in glass smelting furnaces. April 16

COMPLETE SPECIFICATION ACCEPTED.

1885.

7100 W. R. Readwin. Hacking or grounding glass by working or blending powdered metals thereon, and imparting a metallic lustre thereto. March 30

IX.—BUILDING MATERIALS, CLAYS, MORTARS, AND CEMENTS.

APPLICATIONS.

4215 J. Brierley, Halifax. Improvements in floors of wood and earthenware combined. March 26
 4281 W. Hollier, London. Improvements in brick-moulding machines. Complete specification. March 26
 4330 G. H. Couch, London. Improvements in and applicable to brick, stone, terra-cotta, concrete, or other walls. March 27
 4331 G. H. Couch. Improvements in roofing tiles and flushing tiles around chimneys and party and parapet walls. March 27
 4332 G. H. Couch. Improvements in ridge, hip and wall tiles. March 27
 4872 D. Cottier, London. Improvements in the production of imitations of stone, marble, terra-cotta, and such like, for the decoration of buildings, statuary, and other surfaces. April 7
 4977 G. Spink, London. Improving the manufacture of bricks by means of a bottom panel, the effect of which is to economise the consumption of raw material, and improve the surface and quality of the brick, and facilitate the drying of the brick. April 9
 5189 W. Benson and L. Gunning, London. Improvements in means for imparting surface designs or patterns to bricks, tiles, and other like articles. April 11
 5321 M. Hussey, London. Improvements in roofing and other tiles. April 16

COMPLETE SPECIFICATIONS ACCEPTED.

1885.

5001 W. R. Lake—Communicated by A. van Berkel. Preservation of wood blocks for paving purposes. March 30
 6025 W. Montgomery. Fire-resisting cement. March 30
 7082 J. F. Ebner. Adhesive anti-dry-rot composition for securing parquet flooring to stone, etc.
 7189 W. Joy. Manufacture of cement, and apparatus therefor. April 2
 7311 G. M. Garrard. Presses for pressing tiles. March 26
 7339 H. R. Snelgrove. Fire-proof ceilings and floors, and blocks or tiles therefor. April 9
 7967 A. H. Stott, J. A. Stott, and A. H. Stott, jun. Fire-proof flooring. April 9

8306 H. R. Vaughan. Mouthpieces and dies for machines, etc., for manufacturing bricks from plastic clay. April 20
 12383 A. C. Ponton. Manufacture of artificial stones and concretes. April 6

1886.

189 L. J. Cadwell. Drying apparatus, chiefly for granular, pulverulent, and similar substances. March 30
 1912 G. Wooliscroft and T. Freeman. Machinery for and method of constructing tiles of an improved construction. April 20
 2659 C. Spaekman. System of drying the prepared mixture of raw materials for the manufacture of Portland cement. March 26

X.—METALLURGY, MINING, ETC.

APPLICATIONS.

4020 G. Chapman, Glasgow. Preparing purple ore or other fine ore of iron for smelting. March 23
 4054 C. L. Hartsfeld, London. Portable blast furnace plant. Complete specification. March 23
 4113 G. Dyson, Leeds. Apparatus for securing the chaplets used in supporting cores for castings. March 21
 1177 J. W. Wailes, Liverpool. Improvements in and in connection with furnaces and regenerators for use in the production of steel. March 25
 4200 A. H. Anderson and J. Noad, London. Improvements in and connected with the extraction of gold and other precious metals from ores and other substances or products containing such metals. March 25
 4340 A. Beaudry and F. H. Cunningham, London. Improvements on power hammers for forging iron and steel. March 27
 4369 T. H. Johns, London. Improvements in process and machinery for cleaning tin andterne plates. March 29
 4379 C. T. Cayley, London. Improvements relating to the hardening or tempering of steel bullets or projectiles and similar articles, and to apparatus therefor. March 29
 4536 W. Penrose and W. Hackney, Swansea. Improvements in the manufacture of open hearth steel. April 1
 4631 D. Williams, Swansea; and E. Jones, Lee. Apparatus for cleaning tin,terne, and metal plates. April 2
 4695 J. Noad, London. Improvements relating to the extraction or separation of gold, silver, and platinum from ores and other substances or products containing such metals. Complete specification. April 3
 4723 F. Fenwick, London. Improvements in the treatment of waste tin cuttings. April 5
 4750 J. W. Hall, London—Communicated by G. T. Lewis, United States. An improved process for treating lead and other ore for obtaining the metal therefrom, and for the manufacture of white pigment. Complete specification. April 5
 4800 R. Applegarth, London. Improvements in the manufacture of cores for use in the casting of metals. April 6
 4830 C. L. J. Beech, London. Improvements in the manufacture of tungsten compounds. April 6
 4955 H. Kesterton, Birmingham. Improvements in the manufacture of metallic alloys. Complete specification. April 9
 5060 C. M. Pielsticker, London. Improvements in machinery for the production of bars and plates of steel (and of other metals) direct from the molten metal. April 12
 5142 H. Hall, London. Improvements in the process and apparatus for coating metal plates and sheets with tin,terne, or other metals. April 13
 5222 J. Heath and W. Frost, London. Improvements in blasting and shot firing in mines and in appliances relating thereto. Complete specification. April 14

COMPLETE SPECIFICATIONS ACCEPTED.

1885.

5262 T. Nordenfelt. Furnaces for burning naphtha or other volatile liquids, and especially applicable for melting metals difficult of fusion. March 26
 6353 H. J. Haddon—Communicated by J. Wezel. Apparatus for coating, roughening, or graining metal plates. March 26
 7115 W. Beatson. Improved method of blasting in mines. April 20
 7179 J. H. Johnson—Communicated by La Société Anonyme Le Ferro Nickel. Manufacture or treatment of iron and steel. March 30
 7802 E. Fletcher. Eliminating impurities from pig-iron during its conversion into malleable iron or steel. April 9
 7880 J. P. Reitz. A new bronze. April 9
 12823 W. C. Stiff and H. B. S. Bennett. Manufacture of tubes and ordnance of steel and iron. April 13
 11276 W. E. Everitt. Casting hollow metallic ingots for the manufacture of tubes, and moulds therefor. April 2

1886.

27 F. A. Herbertz. Cupola smelting furnaces. March 30
 3702 E. B. Parnell. Treating certain auriferous and argentiferous material to facilitate the separation of the metals contained therein. April 16

XL.—FATS, OILS, AND SOAP MANUFACTURE.

APPLICATIONS.

4068 J. Weineck, London. Improvements in the process of preparing stearic acid. March 23

4064 J. L. Wade, Glasgow. An improved lubricating compound. March 29

4025 T. B. Harrison, London. A new or improved wash or compound for treating, washing, or cleansing painted and other articles or substances requiring such treatment. April 2

4091 J. Higson, Manchester. Improvements in the manufacture of soap particularly adapted for the removal of warts. Complete specification. April 10

5020 A. J. Boulton, London—Communicated by J. Monterrubio, Spain. Improvements in the manufacture of soap and in apparatus therefor. April 10

5239 E. Tucker, Bayhead, Stornoway. Improvements in treating fish curers' and kipper offal for the purpose of obtaining oil and manure therefrom, and for obviating the nuisance that usually arises from such operation. April 15

5277 H. Lambert and G. Greenwood, London. An improved arrangement of apparatus for expressing oil from oil-yielding vegetable substances, and converting the residue into oilcake. April 15

5328 H. Hall, London. Improvements in the preparation of oils, greases, and fats for use in the manufacture of tin andterne plates. April 16

COMPLETE SPECIFICATIONS ACCEPTED.

1885.

5383 A. G. Brooks—Communicated by R. Gieberman. Refining or separating glycerine from fats and oils. April 20

7972 O. C. Hagemann. Purification of glycerine. April 13

7973 O. C. Hagemann. Purifying and concentrating glycerine, etc. April 20

8054 O. C. Hagemann. Treating soap-leys to obtain products therefrom. April 20

XII.—PAINTS, VARNISHES, AND RESINS.

APPLICATIONS.

4750 J. W. Hall, London—Communicated by G. T. Lewis, United States. An improved process for treating lead and other ore for obtaining the metal therefrom, and for the manufacture of white pigment. Complete specification. April 5

5270 J. B. Melvin, London. Improvements in the manufacture of resinous compounds. Complete specification. April 15

COMPLETE SPECIFICATIONS ACCEPTED.

1885.

1604 T. J. Pearce and M. W. Beardsley. Rendering substances impermeable to air and liquids, and producing a compound suitable for use as an antifouling paint, and in electrical insulation. April 2

8008 P. C. Bunn. Manufacture of pigments from by-products or waste of lead ores. April 16

XIII.—TANNING, LEATHER, GLUE, AND SIZE.

APPLICATIONS.

4277 T. T. Marshall, Canada. Crimping leather. March 26

5019 H. S. Burrow, Nottingham. Improvements in machines for grounding and softening skins or leathers. Complete specification. April 12

5417 J. Palmer, London. Improvements in the process of unhairing or unwooling hides and skins, and preparing them for tanning. April 19

COMPLETE SPECIFICATIONS ACCEPTED.

1885.

7462 T. Nordenfelt. Manufacture of blood albumen. April 9

7818 A. Johnson. Manufacturing and treating leather. April 2

XIV.—AGRICULTURE, MANURES, ETC.

APPLICATIONS.

1526 H. Stevenson and E. J. Theodora Digby, London. Improved artificial manures. March 31

4797 P. Wilson, Glasgow. Improvements in apparatus for distributing artificial manures or other granulated substances. April 6

XV.—SUGAR, STARCHES, GUMS, ETC.

APPLICATIONS.

1328 S. Banner, Liverpool. Improvements in or relating to the dissolving or combining of indiarubber and other like gums, and to the application of compounds so formed to industrial purposes. March 27

4398 A. Rossi and C. Heilfrisch, London. Improvements in the manufacture of dextrine. March 29

4516 P. Jensen, London—Communicated by M. C. P. Barbe, Holland. Improvements in apparatus for the manufacture of refined sugar. Complete specification. March 31

4679 C. W. N. Wallace and C. J. H. Barry, London. Improvements in the manufacture of caramel. April 3

4891 C. D. Abel, London—Communicated by P. S. Sobue, Germany. Improved process for the desaccharification of molasses and sugar-syrups and the simultaneous production of oxalates from the salts contained therein. April 6

4918 O. Inray, London—Communicated by A. K. Kissel, Germany. Manufacture of an elastic compound in imitation of caoutchouc. April 8

5111 J. D. Scott and A. Scott, Glasgow. Improvements in purifying or refining saccharine liquids or syrups. April 13

5399 J. Swindlehurst, Barrow-in-Furness. The "Swindlehurst" patent impervious elastic composition. April 19

COMPLETE SPECIFICATIONS ACCEPTED.

1885.

8000 A. Seyberlich and Trampedach. Manufacture of crystallised grape sugar. April 16

1886.

3727 H. H. Lake—Communicated by La Société Nouvelle des Raffineries de Sucre de St. Louis. Refining sugar, and apparatus therefor. April 16

XVI.—BREWING, WINES, SPIRITS, ETC.

APPLICATIONS.

4071 F. Faulkner and W. Adlam, London. Improvements in aerating brewers' wort and other liquids, and in machinery or apparatus therefor. March 23

4168 W. Spencer and J. Jones, Liverpool. Improvements in the treatment of brewers' worts. March 25

4191 W. A. How, New Malden. Improvements in apparatus and mode of holding or containing therein bicarbonate of soda for generating carbonic acid gas to be used in aerating draught ale or other beverages. March 25

4311 W. W. Crawford, Glasgow. Improvements in maturing alcoholic liquors. March 27

4529 E. L. Pontifex, London. An improved skimmer or apparatus for removing yeast from wort in a fermenting vessel. March 31

4532 E. Hawker, London. A non-intoxicating drink or beverage. March 31

4868 W. Bradford, London. Improvements in cowl especially applicable for malt or other kilns and brewing and distilling utensils. April 6

4919 G. Epstein, London. Improvements in the treatment of yeast. April 8

5071 W. T. Ramsden, London. Improvements in bottling beer and other fermented drinks. April 12

5152 F. Pigeon and W. L. Flanagan, London. Improvements in the manufacture of ale, beer, and porter. Complete specification

5211 J. Hill, London. An improved hydro-pneumatic apparatus for raising or forcing beer or other liquids, applicable also for motive-power purposes. Complete specification. April 14

XVII.—CHEMISTRY OF FOODS, SANITARY CHEMISTRY, DISINFECTANTS, ETC.

APPLICATIONS.

A.—CHEMISTRY OF FOODS.

4062 J. Y. Johnson, London—Communicated by C. Marchaud, United States. Improvements in and apparatus for the treatment of rancid butter and other materials, for purifying, flavouring and mixing the same or the like. Complete specification. March 23

4114 A. S. Krueger, Lenzie, near Glasgow. A preparation for a new beverage similar to coffee. March 24

4207 L. C. Marshall, Glasgow. Improvements in the preparation of animal substances for use as food. March 25

4320 W. W. Nightingale, London. Improvements in the manufacture of transparent ice. March 27

4578 T. D. Lawson and L. C. Marshall, Glasgow. Improvements in the preparation of animal substances for use as food. April 1

4539 R. Ashton, Heaton Mersey. An improved method of preserving eggs. April 2

4989 F. W. Wendenburg, London. An improved process for manufacturing food for cattle and other animals from woodmeal or powder. Complete specification. April 10

B.—SANITARY CHEMISTRY.

4203 L. G. Ghilain, Liverpool. Improvements in the purification and utilisation of sewage, and apparatus therefor. March 25

4512 F. Petri, London. Improvements in the disinfection of sewage, waste liquors, and the like. March 31

4541 T. Reid, Normanton. Apparatus for and mode of clarifying sewage and filtering large volumes of water. April 1

4609 T. G. Hardie, Burnley. The combustion and destruction of town refuse and other matter, also as a crematory—a special form of furnace. April 1

4623 P. Hickey and J. Radcliffe, Manchester. An improved filter for the purification of water and other liquids. April 2

4667 G. M. Nicolans, London. Apparatus for giving off exhalation from tar. April 3

4878 W. F. B. Massey-Mainwaring, London. Improvements in or connected with filter-presses, and in the drying of sewage sludge and other moist matters. April 7

C.—DISINFECTANTS.

4117 A. L. Dussek, London. Improved means for producing antiseptics and disinfectants. Complete Specification. Mar. 24

4551 H. H. Lake, London—Communicated by F. L. Sarmiento, W. G. Grimm, S. P. Sadler, F. J. Sarmiento, and J. A. Wiedersheim, United States. Improvements in disinfecting compounds. Complete specification. April 13.

COMPLETE SPECIFICATIONS ACCEPTED.

A.—CHEMISTRY OF FOODS.

9216 E. Whillier. Apparatus for preserving articles of food. April 9

B.—SANITARY CHEMISTRY.

1885.

6351 A. Howatson, London. Apparatus for separating solid impurities from water or other liquid. March 26

7416 P. A. Maignen. Water softening processes. March 30

7703 B. D. Heatey. Furnaces for burning towns' refuse, and decomposing the fumes therefrom. April 13

7714 P. Smith. Means and apparatus for separating solids and semi-solids from sewage, etc. March 30

7759 J. M. H. Muir, S. H. Johnson, and C. C. Hutchinson. Treatment of sewage. April 9

8183 J. B. Allott. Apparatus for treating the mud, slop, or sweepings removed from roads, etc. April 20

8912 J. B. Spence. Treatment of sewage at or near the outfall. April 6

1886.

2721 R. de Soldenhoff. Furnaces for the desiccation, etc., of precipitants or solids from sludge, or other putrescible substances. April 16

C.—DISINFECTANTS.

1886.

2780 J. G. Swan and R. M. W. Swan. A sheep-dipping and disinfectant composition. March 26

XVIII.—ELECTRO-CHEMISTRY.

APPLICATIONS.

4057 P. Haddan, London—Communicated by J. Crosse, France. Improvements in voltaic piles and accumulators. March 23

4132 M. Bohdanecky and J. Nesetrl, London. Improvements in dynamo-electrical machines. March 24

4214 C. Wells, London. Improvements in electric baths. March 25

4352 T. J. Jones, London. Improvements in voltaic batteries. March 27

4453 M. Bailey and J. Warner, London. Improvements in electrical cells or batteries. March 30

4522 W. S. Squire, London. A process for utilising the spent liquid from certain voltaic batteries. March 31

4523 H. Müller, London. An improvement in induction apparatus or secondary generators. Complete specification. March 31

4553 W. A. Thoms, London. Improvements in the deposition of platinum by electricity. April 1

4555 A. le Neve Foster and F. V. Anderson, London. Improvements in the distribution of and apparatus for transforming continuous electrical currents. April 1

4575 W. J. S. Barber-Starkey, London. Improvements in secondary batteries. April 1

4680 J. D. F. Andrews, London. Apparatus for altering the potential of electrical currents. April 2

4682 F. King, London. Improvements in the automatic electrical distribution and charge of secondary batteries. April 2

4683 F. F. Stögermayr and V. Glassner, London. Improvements in electric generators. April 2

4751 H. S. Maxim, London. Improvements relating to the application and utilisation of magnetism or electromagnetism for the separation of metals and for other purposes, and to apparatus therefor. April 5

4809 W. P. Thompson, Liverpool—Partly communicated by The Cowles Electric Smelting & Aluminium Co., United States. Improvements in or relating to electric furnaces on the "Cowles" principle, to the manufacture of chemicals by means of such furnaces, and to the utilisation of a substance obtainable thereby. April 6

4884 J. Platt, J. Hopkinson, and E. Hopkinson, London. Improvements in dynamo-electric machines. April 7

4937 W. R. Lake, London—Communicated by W. E. Case, United States. Improvements relating to the conversion of heat energy into electrical energy, and to apparatus therefor. Complete specification. April 8

5090 H. Serrin and F. Fesquet, London. Improvements in apparatus for measuring the consumption of electricity. April 12

5092 A. Rüst, London. Improvements in thermo-electric generators. April 12

5176 C. L. Baker, Manchester. Improvements in dynamo-electric and electro-dynamo machines. April 11

5215 A. Campbell. Improvements in electrical batteries. April 11

5218 B. Pell, London. An electrometer. April 11

5223 P. Ward and Sir S. J. Blanc, London. Improvements in insulating materials for electrical purposes. April 11

5273 H. P. Holt, London. Arrangement for mounting and driving dynamo-electric machines. Complete specification. April 15

5298 C. Moseley, Manchester. Improvements in and relating to secondary voltaic battery. April 16

5338 W. T. Goolden, A. P. Trotter, and H. W. Ravenshaw, London. Improvements in means or apparatus for governing dynamo and other machines. April 16

5409 L. Bollmann, Vienna. Improvements in dynamo machines and electric motors. April 19

COMPLETE SPECIFICATIONS ACCEPTED.

1885.

3941 J. Swinburne, Brockley. Dynamo electric machines. March 26

4671 D. G. Fitz-Gerald. Manufacture of elements for voltaic batteries. April 13

5123 W. H. Allen, R. Wright, and G. Kapp. Exciting the field magnets of series-wound dynamo machines. March 30

5491 C. A. A. Capito and M. P. Hardt. Dynamo machines and electro motors. March 30

6037 M. Immisch. Electro motors and dynamo machines. March 30

6325 T. Parker. Dynamo-electric machines. April 6

6964 G. F. Redfern—Communicated by J. B. Neyraud. Electric batteries. April 20

7114 G. E. Dorman. "Gramme" armatures for electric generators and motors. April 16

7733 H. C. B. Chalders and A. J. Thorman. Electrical batteries. March 30

8228 H. I. Harris. Voltaic batteries. April 20

8416 A. Khotinsky. Constructing electrode frames for secondary voltaic batteries. March 30

9302 A. H. Upward and C. W. Fridham. Galvanic batteries. March 30

11629 B. M. Drake and J. M. Gorham. Instruments for measuring electric currents. April 16

1886.

932 A. Le Neve Foster and F. V. Anderson. Improvements in dynamo-electric machines, and in the transmission of power therefor. March 26

1493 H. J. Allison—Communicated by W. L. Voelker. Dynamo-electric machines and motors. March 26

3726 H. H. Lake—Communicated by J. Serson. Galvanic batteries. April 16

XIX.—PAPER, PASTEBOARD, Etc.

APPLICATIONS.

4050 R. Horrox, Liverpool. Improvements in the manufacture of paper, and in apparatus therefor. March 23

4934 J. B. Seammell, London. Improvements in the manufacture of paper for cigarettes. April 8

COMPLETE SPECIFICATIONS ACCEPTED.

1885.

6840 R. C. Menzies, C. F. Cross, and E. J. Bevan. Treatment of fibrous substances for the manufacture of paper pulp and textile fabrics. March 30

7495 H. J. Haddan—Communicated by C. H. Voigt. Preparing fodder from certain waste products obtained in the manufacture of cellulose or paper pulp. April 13

8073 C. C. Springer. Construction of boilers for treating wood and other fibre in the manufacture of paper and other pulp. April 20

10543 C. J. Richardson. Apparatus for the manufacture of paper. March 30

XX.—FINE CHEMICALS, ALKALOIDS,
ESSENCES, AND EXTRACTS.

APPLICATION.

4392 A. Morand, London. Improvements in the manufacture of tannin extract and similar vegetable extracts, and in apparatus employed therein. March 29

COMPLETE SPECIFICATIONS ACCEPTED.

7527 H. N. Draper, Rathmines. Preparation of a colourless or decolourised solution of iodine. Date ?

7113 D. B. Dott. The artificial production of codeia. April 2

XXI.—EXPLOSIVES, MATCHES, Etc.

APPLICATIONS.

1116 J. Farnsworth, Manchester. Manufacturing a friction signal and destructive bomb, called "The friction bomb." March 21

4265 H. C. Seddon, London. Improvements in percussion fuses for projectiles. March 26

4525 G. A. Sweetser, London. Improvements in the manufacture of cigar lights, fuses, or vesuvians, and apparatus therefor. March 31

4791 H. Schwoneweg, London. Improvements in explosives. April 6

5330 H. E. Newton—Communicated by A. Nobel. Improvements in the manufacture of explosive compounds. April 16

5331 H. E. Newton—Communicated by A. Nobel. Improvements in the manufacture of explosive substances. April 16

5385 R. Cole Gardner, London—Communicated by T. Gibson, France. Improved compounds or ingredients for producing explosions or expansive action in engines for motive-power purposes, and in parts of engines therefor. April 17

COMPLETE SPECIFICATIONS ACCEPTED.

1885.

6591 H. S. Maxim. Improvements in guns and explosive projectiles therefor. April 6

8137 O. Jones. Percussion fuses. April 16

THE JOURNAL OF THE Society of Chemical Industry:

A MONTHLY RECORD

FOR ALL INTERESTED IN CHEMICAL MANUFACTURES.

No. 5.—VOL. V.

MAY 29, 1886.

Non-Members 30/- per annum; Members
21/- per Set; Single Copies 2/6.

The Society of Chemical Industry.

Past Presidents:

Sir H. E. Roscoe, M.P., LL.D., V.P.R.S.	1881—1882.
Sir Frederick Abel, C.B., D.C.L., F.R.S.	1882—1883.
Walter Weldon, F.R.S.	1883—1884.
W. H. Perkin, Ph.D., F.R.S.	1884—1885.

COUNCIL FOR YEAR ENDING JULY, 1886.

President: E. K. Muspratt.

Vice-Presidents:

Sir F. A. Abel, C.B., D.C.L., F.R.S.	Peter Griess, Ph.D., F.R.S.
Sir I. Lowthian Bell, Bart., F.R.S.	W. H. Perkin, Ph.D., F.R.S.
Alexander M. Chance.	Sir H. E. Roscoe, M.P., F.R.S., LL.D., V.P.R.S.
Prof. James Dewar, F.R.S.	John Spiller.
James Duncan.	E. C. C. Stanford.
David Gamble.	J. C. Stevenson, M.P.

Ordinary Members of Council:

R. Forbes Carpenter.	S. A. Sadler, Ph.D.
Henry Doulton.	Sir Bernhard Samuelson, Bart., M.P.
John Evans, D.C.L., F.R.S.	Sir Chas. Tennant, Bart., M.P.
Ivan Levinstein.	Prof. W. A. Tilden, F.R.S.
Rudolph Messel, Ph.D.	John Williams.
B. E. R. Newlands.	
Thomas Royle.	

With Sixteen Chairmen and Secretaries of Sections.

Honorary Treasurer:

E. Rider Cook, M.P., East London Soapworks, Bow, E.

Honorary Foreign Secretary:

Ludwig Mond, 20, Avenue Road, Regent's Park, N.W.

General Secretary: Charles G. Cresswell.

Offices:

Palace Chambers, 9, Bridge Street, Westminster, S.W.

THE JOURNAL.

Publication Committee:

The President.

NOTICES.

ANNUAL GENERAL MEETING.

The next Annual General Meeting of the Members of the Society of Chemical Industry will be held in Liverpool on Wednesday, Thursday, and Friday, July 14, 15, and 16 next.

PROGRAMME OF PROCEEDINGS.

At 11 a.m. on the morning of Wednesday, July 14, the Members will meet in the new Chemical Theatre of the University College, Brownlow Street, to transact the ordinary business of the Society, to elect Office-bearers, and to hear an address by the President. By permission of the College Authorities, Members will have an opportunity of inspecting the new laboratories, both before and after the meeting. In the afternoon alternative excursions have been arranged to the following places of interest:—(a) The International Exhibition; (b) The Liverpool Gasworks; and (c) other works in the city, particulars concerning which will be duly announced on the time-card inserted in the June issue of the Journal. In the evening, at 7 p.m., the Annual Dinner will take place at the Adelphi Hotel. Dinner tickets, 10s. 6d. each (exclusive of wine), may be obtained on application, accompanied by remittance, to the Honorary Secretary of the Liverpool Section, Mr. W. P. Thompson, 6, Lord Street, Liverpool. Application before July 2 is requested.

Thursday, July 15.—At 10.30 a.m. Members will proceed to inspect the Albert Dock warehouses. At 12.30 they will embark on a special steamer for a sail up the Mersey; lunch will be provided on board. On returning, Members will disembark at the new North Dock to inspect—(a) the Graving Docks, with their hydraulic machinery; (b) the new grain silo warehouses and elevator; and (c) a transatlantic steamer. At 3.30 p.m. Members will re-embark to pay a visit to one of the following:—(a) The Great Float, Birkenhead; (b) Messrs. Laird's Shipbuilding Works; returning home by the Mersey Tunnel or by ferry as preferred. In the evening, at 8 p.m., there will be a *Conversazione and Reception* by the President at the Walker Art Gallery and Picton Reading Room.

Friday, July 16.—In the morning excursions will be made to Widnes and St. Helens; and in the afternoon to Crewe Railway and Steel Works.

Members are specially requested to note that the date of the Meeting has been changed from July 7, 8, and 9 to Wednesday, Thursday, and Friday, July 14, 15, and 16.

In accordance with the provisions of Rule 18 of the Bye-laws, notice is hereby given that those Members of

Council whose names are placed in italics in the annexed list, will retire from their respective offices at the forthcoming Annual General Meeting.

Mr. David Howard has been nominated to the office of President, and Mr. E. K. Muspratt has been nominated Vice-president under Rule 11.

Sir H. E. Roscoe, M.P., has been nominated Vice-president under Rule 24; Dr. Ferdinand Hurter, Mr. John Williams, and Mr. Philip Worsley have been nominated Vice-presidents under Rule 8; and Mr. Eustace Carey has been nominated Ordinary Member of Council under Rule 17, in the place of Mr. John Williams, nominated Vice-president.

The Treasurer and Foreign Secretary have been nominated for re-election.

Members are hereby invited to nominate fit and proper persons to fill four vacancies among the Ordinary Members of Council under Rule 18. Special nomination forms for this purpose can be obtained from the General Secretary upon application.

Extract from Rule 18.—"No such nomination shall be valid unless it be signed by at least ten members of the Society, who are not in arrear with their subscriptions, nor unless it be received by the General Secretary, at the Society's Office, at least one month before the date of the commencement of the Annual General Meeting, to the election to take place at which it refers. Nor shall any such nomination be valid if the person nominated be ineligible for election under Rules 12 or 15. No member shall sign more than one nomination form."

PROPOSED AMENDMENT OF BYE-LAWS.

Notice is hereby given, in accordance with Rule 54, that it will be proposed to the forthcoming Annual General Meeting to further amend the Society's Bye-laws as follows:—

Bye-law 1.—That the words "and is established in accordance with the provisions of the Literary and Scientific Institutions Act, 1854," be added after the word "Industry."

Bye-law 5.—That the word "or" be inserted in the third line thereof between the words "Council" and "a professional."

Bye-law 27.—That the words "One Guinea" in the first line thereof, be replaced by the words "Twenty-five Shillings."

Bye-law 29.—That the words "is more than four months in arrear," in the second line thereof, be replaced by the words "has not been paid."

Bye-law 37.—That the word "President" in the second line thereof, be replaced by the word "Chairman."

Bye-law 42.—That the words "is in arrear with" be replaced by the words "has not paid."

Bye-law 49.—That the date "31st of December" be replaced by the date "15th of June."

Bye-law 54.—That the word "given" in the last line but one thereof, be replaced by the word "posted."

The supply of copies of the Journal for January, 1882, being now exhausted, the Secretary would be glad to receive communications from members possessing extra copies of that number, in good condition, with a view to purchase.

Should sufficient applications for complete sets be received, the number will be reprinted.

In reply to numerous inquiries, members are hereby informed that no tickets for the Colonial Exhibition have been supplied to the Secretary.

CHANGES OF ADDRESS.

C. M. Aikman, 1/o Partick Hill; 183, St. Vincent Street, Glasgow.

Thos. Akitt, 1/o Lenzie; c/o The Indigo Co., Limited, Behar, Bengal, India.

A. H. Allen, 1/o Ash Mount; Sydenham Cottage, Park Lane, Sheffield.

J. H. Beckett, 1/o Miles Platting; Wilmslow Park, Cheshire.

J. Beveridge, 1/o Cardiff; Erishkoff's Works, Elabrya, Govt. Viatka, via Moscow, Russia.

L. Briant, 1/o Graecchurch Street; 24, Holborn Viaduct, London, E.C.

H. J. Chaney, 1/o Sheffield; North Mexican Silver Mining Co., Cusuhuiriac, Chihuahua, Mexico (via New York and El Paso).

T. J. Flynn, 1/o Guide Bridge; c/o D. Haywood & Sons, Mitcham, Surrey.

S. A. Goldschmidt, 1/o Water Street; Columbia Chemical Works, 29–30, Jay Street, Brooklyn, U.S.A.

G. J. Hamden, 1/o Midcalder; 33, Vane Street, Spring Bank, Hull.

P. Hart, 1/o Ardwick; c/o Tennants & Co., Mill Street, Clayton, Manchester.

W. E. Heys, 1/o Chorlton; 70, Market Street, Manchester.

J. T. Irwin, 1/o Cheetam; The Grange, Polygon Road, Higher Crumpsall, Manchester.

Wilf. Irwin, 1/o Cheetam; The Grange, Polygon Road, Higher Crumpsall, Manchester.

W. J. Johnston, 1/o Thynne Street; 37, Bewsey Street, Warrington.

Wm. Jones, 47, New Broad Street—Journals to c/o Herb. Jones, 6, Lord Street, Liverpool.

W. H. Lake, 1/o Knight's Hill; 11, St. Julian's Farm Road, West Norwood, S.E.

S. D. Leah, 1/o Nottingham; 18, Applegarth Road, Brook Green, Hammersmith, W.

T. Macfarlane, 1/o Montreal; Inland Revenue Dept., Ottawa, Canada.

G. D. Mease, 1/o Tulse Hill; 2, Montrell Road, Streatham Place, London, S.W.

D. Melville, 1/o Kilby Street; 13, Pearl Street, Boston, Mass., U.S.A.

J. M. Milne, 1/o West Regent Street; Royal Infirmary Medical School, 87, Castle Street, Glasgow.

J. J. Morgan, 1/o Rhymney; c/o Jno. Parry, Highfield House, Ebbw Vale, Monmouth.

W. Johnston Saint, 1/o Hess Strasse; Hermann Strasse 5, Schwabing, Munchen, Bavaria.

W. J. Taylor, 1/o Graecchurch Street; c/o L. Briant, 24, Holborn Viaduct, London, E.C.

E. F. Trachsel, 1/o Meath; 14, Walter's Terrace, Swansea.

C. T. Wilson—Journals and communications to 16, Gordon Square, London, W.C.

MEMBER RESTORED ON PAYMENT OF ARREARS.

C. A. Serré, 55, Fulton Street, New York, U.S.A.

CHANGES OF ADDRESS REQUIRED.

W. B. Albright, 1/o Dorchester, Mass., U.S.A.

J. Clark, 1/o 35, Mariners' Cottages, South Shields.

H. W. Fenner, 1/o 7, Vanbrugh Park Road, Blackheath, S.E.

Thos. Leech, 1/o 5, Rumford Place, Liverpool.

LIST OF MEMBERS ELECTED, 24th MAY, 1886.

J. Williams Bevan, Southview House, Shirehampton, near Bristol, lead smelter.

W. W. Butler, Crown Brewery, Broad Street, Birmingham, brewers' analyst.

Aug. H. Gill, Mass. Inst. of Technology, Boston, Mass., U.S.A., assistant in sanitary chemistry.

Martin L. Griffin, Holyoke, Mass., U.S.A., practical chemist.

W. Hogben, Redbraes, Broughton Road, Edinburgh, analyst.

H. G. Holdsworth, West Ham Abbey, London, E., candle maker and wax refiner.

Walter Jackson, 24 Sydenham Avenue, Sefton Park, Liverpool, metallurgical chemist.

G. Jacques, High Street, Uttoxeter, North Staffordshire, pharmacist.

H. L. Lilley, Albert Works, Queen's Road, Manchester, starch and gum manufacturer.

J. A. Meynier, 8, Rue Parc Royal, Paris, chemical merchant.

O. V. Morgan, M.P., 13, The Boltons, South Kensington, S.W., crucible manufacturer.

A. G. Phillips, 20, Canning Street, Liverpool, manager, Widnes Metal Co.

A. Twikey, 392, Coventry Road, Birmingham, pharmacist.

C. N. Waite, Medford, Mass., U.S.A., analytical chemist.

F. T. Walsh, Hamilton Printworks, Lowell, Mass., U.S.A., colourist.

E. H. Winstone, 24, Belgrave Road, London, S.W., colour, ink, and paint manufacturer.

Jas. Wood, Foxhill Bank Printworks, Church, near Accrington, manager.

Wm. Wood, Antwerp, Belgium, bleacher and dyer.

Wm. H. Woodcock, 13, University Place, New York, U.S.A., manufacturing chemist.

Hikokuro Yoshida, Imperial University, Hongo, Tokyo, Japan, assistant professor of chemistry.

London Section.

CHEMICAL SOCIETY'S ROOMS, BURLINGTON HOUSE.

Chairman: David Howard.

Local Sec. and Treasurer: Thos. Tyrer,
Garden Wharf, Church Road, Battersea, S.W.

MEETINGS, SESSION 1885-86.

ORDINARY MEETING POSTPONED TILL TUESDAY,
JUNE 8.

June 8.—Dr. Meymott Tidy — "Chemical Treatment of Sewage."

July 7, 8 and 9.—Annual Meeting at Liverpool.

Notices of papers and communications for the meetings to be sent to the Local Secretary.

Meeting held Monday, May 3, 1886.

DAVID HOWARD, ESQ., IN THE CHAIR.

THE PURIFICATION OF WATER.

BY A. GORDON SALAMON, A.R.S.M., F.C.S.; AND W. DE
VERE MATHEW, F.I.C.

THE many discoveries recorded in the comparatively modern science of bacteriology, have already provided chemists with the nucleus of an accurate method for estimating the number of organisms in water. The conception of such a process must probably be credited to Angus Smith; but its development and extended introduction is without doubt the result of the researches of Koch, and of the painstaking and laborious work of Percy Frankland. We say that as yet we have only been provided with the nucleus of a method; because, within very restricted limits, it is almost impossible to deduce any really reliable inferences from the experiments, which reveal—doubtless with sufficient accuracy—the presence of the organisms in water. We know that many kinds of organisms may be conveyed into the system in vast quantities, without producing any harmful effect whatever; and we also know that others, if so introduced, will be responsible for the propagation of most serious illnesses. Thus, it is conceivable that a water may contain thousands of harmless germs, and a very minute proportion of disease ensues; and that the few among the thousands may be responsible for injurious effects produced by drinking the water in question. Hence, in the absence of other data, it would seem somewhat premature to condemn a sample of water because it is proved to contain an abnormally large number of organisms. The experiments which prove this require supplementing by others, which will allow of the differentiation of germs which are harmless from those which are injurious; and chemists are, unfortunately, yet without the means of effecting this desirable separation. But there are many facts which would seem to indicate that such a method will eventually be found; and already observations have been accumulated, the accurate interpretation of which may subsequently serve to throw much light upon this branch of the subject. For instance, it has been proved that some organisms, when properly submitted to the process of plate cultivation, will develop colonies which tend to liquefy the medium in which they thrive, whereas others exhibit no especial ten-

dency in this direction. It would seem that colonies which manifest this particular tendency, must have different modes of life, and must excrete different products, from those which do not liquefy; and it would be interesting to know whether those colonies which liquefy are more associated with disease germs than are those which keep the gelatine solid at the temperature of incubation. Such information might probably be gained by inoculating sterilised water with definite disease cultures, and noting the characteristics of the colonies so produced. In any case, we think that chemists and medical men will hesitate to condemn a water as unfit for use because of the large number of colonies which may be developed from it, until such time as they can obtain some reliable information as to the nature and potential influences of the germs which constitute the colonies in question. We are disposed, then, for these and other reasons, upon which we refrain from enlarging, to regard what we may term the bacteriology of water as being still in its infancy; but we do not for one moment deny that it has already been made to yield results which are of the greatest possible practical value. It has, undoubtedly, been made to constitute a fairly accurate test of the amount of filtration to which waters supplied by the London companies have been subjected from month to month; but above all it has been made a means of affording remarkable evidence as to the comparative efficiency of various filtering materials. It is to this latter branch of the subject that we are desirous of directing attention, not so much with a view of emphasising any particular work which we ourselves may have done in connection with the subject, as to attempt to correlate the question of the chemical purification of water with that of the removal from it of its contained micro-organisms.

Dr. Percy Frankland has proved that certain filtering materials possess a remarkable power of removing organisms from water, and we have reason to believe that in many cases he regards the action of these filtering materials as being germicidal in nature; whereas, he looks upon others as being merely mechanical in their action. For instance, the Pasteur-Chamberland filter removes the germs from water, and practically sterilises it; but Dr. Frankland has stated that there is no real difference in the chemical composition of the water before and after filtration through the material of which this filter is composed. We take it, then, that such a filter would act mechanically, whereas spongy iron, which exerts a powerful chemical action upon the water, and at the same time very effectually removes the contained organisms, is germicidal in its tendency. Now, Dr. Frankland has—we had almost said carefully—distinguished between the chemical efficiency of a filtering material, and its capacity for removing organisms. In saying this, we mean that he has treated the two questions as being distinct, inasmuch as he has made no serious attempt to correlate them. We shall hope to prove that there is a very close connection between the power of a material for effecting chemical purification of water, and the removal of organisms; and in so doing we are not without hope that we may in some small way contribute towards the establishment of a fundamental theory, which shall explain the true principles embodied in the purification of water, and which may serve as a guide to those who occupy themselves with this, one of the greatest and most important of modern problems.

We can conceive the possibility of germs being mechanically intercepted during the passage of water through a filtering material; and we can further conceive the possibility of their becoming embodied in a precipitate, which is brought into contact with a water, and is subsequently removed from it. Dr. Frankland

has in several cases indicated that this tendency actually exists; but we cannot regard such a purification as satisfactory, because it does not remove the nutritive materials which are essential to the development of the organisms; and, further, because it may permit of the passage of the more minute spores, which would perhaps escape recognition owing to their not making their appearance upon the gelatine plate within the limits of time permitted to the more fully developed organisms. If sterilisation be effected in this manner, it can at best be regarded as a makeshift purification. It will be admitted that organisms will not multiply without the presence of organic material, which can be broken down for food; and unless this material is removed or rendered incapable of assimilation, we cannot regard the water as being satisfactorily purged of its impurities. On the other hand, if chemical purification be effected, without accompanying germ removal, then we freely admit that it would be far worse than germ removal without chemical purification; and it therefore becomes necessary, in order to obtain the requisites of a theoretically perfect filter, to ascertain the conditions which will permit of both.

It will be advisable, before proceeding further, to attempt to formulate the conditions which permit of chemical purification, and to inquire how these conditions are reconcilable with the experiments and results which we have obtained in the laboratory. It would appear to us that there are but two conceivable actions upon which chemical purification can depend:—

1. It may be the result of a contact action, in which the filter constitutes the catalytic agent. In such a case the filter itself would not undergo change, although it would, by its presence, induce a change in the composition of the organic constituents of the water. Such an action would be analogous in every respect to others which have been recorded in connection with chemical change. Thus, if carbonic anhydride be passed through a hot solution of benzene, containing a trace of aluminic chloride, benzoic acid is formed, whereas no such formation takes place if the aluminic chloride be omitted, although the latter itself undergoes no change whatever. Calcic hypochlorite is decomposed, and oxygen liberated, in presence of cobaltic hydrate, which remains unchanged, whereas no oxygen is evolved with the hypochlorite alone. Then there is the well-known action of manganic dioxide in facilitating the decomposition of potassic chlorate; and, lastly, may be mentioned the union of oxygen and sulphurous acid, or of hydrogen and oxygen in the presence of platinum. We have not yet been able to satisfy ourselves as to whether contact action does or does not play any part in the chemical purification of water. We may possibly be in a position to give some further information upon this point at some future date; and more especially do we hope to be able to do this in connection with the influence of platinised asbestos as the catalytic agent.

2. The filter must itself be capable of undergoing chemical change when in contact with water.

The nature of this change may obviously vary within very wide limits; but, as the result of many experiments, we are inclined to think that liability of filtering material, or, at least, of one of its constituents, to undergo oxidation, is one of the most important essentials to chemical purification. We are further of opinion that the most efficient filtering material will be that which is capable of undergoing the greatest amount of oxidation in the least amount of time. We believe that it is the dissolved gases in the water which act upon the filtering material and thereby induce the chemical changes in the organic

matter of the water. The tendency of this action would seem to be to convert the carbon of the impurity into carbonic acid, and the nitrogen into ammonia. We have, moreover, reason to believe that if water be completely deprived of its contained gases prior to filtration, no satisfactory purification could be effected. The oxidation, or change, may be obtained by the use of a simple filtering material; or it may preferably be effected by the union of two dissimilar elements, or compounds, one of which is liable to change. The latter class of filtering materials have, in our hands, given decidedly the best results, if we consider them with reference to the combination of sterilisation with purification. It will be apparent that the intimate union of dissimilar elements, or bodies, in presence of a water containing carbonic acid, constitutes the conditions favourable to electrical action; and we have found that where such action existed the tendency of the filter was to exert a maximum purifying effect. Moreover, the experiments of Schönbein and Boillot, of Kingzett, and of Paul Bert, support our view, inasmuch as these show that sterilisation is very satisfactorily produced by the action of an electric current. Now, with a few exceptions, we have found that these simple bodies which are susceptible of ready oxidation, or change, diminish in their purifying capacity with the lapse of time. In other words, they become coated with a layer of oxide or carbonate, which is formed in the act of purification, and, as a rule, the oxide or carbonate so formed is inert as a purifying filter. This difficulty, it would appear, may be surmounted in several ways. There may be such a combination of materials, that whereas one tends to oxidise, the other tends to reduce the product of oxidation as it is formed; or the removal of the oxidised body may be brought about by the agency of an electric current, preferably produced by the action of two dissimilar bodies in close contact. In such a case the constancy of the filter would be maintained by a process of depolarisation. We have also found that an electric current from a battery, in addition to that obtained by the contact of two dissimilar bodies, is of immense service in maintaining the constancy of filtering materials. We confess that our ideas in connection with this theory were very much shaken by some observations which Dr. Percy Frankland has made before this and other Societies respecting the influence of coke in promoting sterilisation. He has shown that it exerts a very powerful effect in this direction, and his observations are amply confirmed by our own experiments. But he has also stated, in effect, that the passage of water through coke exerts no chemical purification whatever.

Now, when we consider the porous nature of coke, and grant that the passage of water through it causes the removal of the germs, and that such removal is not due to any primary absorption, but is continued for months after the coke has been in use, and when we have further to conceive that the organisms can be destroyed, with such certainty, without any accompanying chemical change taking place in the water, we are forced into a position which we find ourselves unable to accept. It would be just as reasonable to conclude that an animal could partake of a food which would cause its death, or could be introduced into a fatally poisonous atmosphere, without any chemical change being induced in its system. It might possibly be that the coke acted as a contact agent, and in so doing induced a chemical change in the composition of the water, which change caused the death of the organisms; but that their mere passage through a porous material, in itself absolutely inert, could induce sterilisation, was to us unintelligible. Hence we felt it necessary at once

to challenge Dr. Percy Frankland's assumptions respecting the absence of chemical change; and we deem it necessary to dwell upon the matter now, because the whole value of our results will hinge upon the question as to which of us be correct upon this particular point. We succeeded in obtaining from Dr. Percy Frankland the statement that his two filtrations, the only ones of which chemical analyses are recorded, were made by passing the water through the filtering material contained in about six inches of ordinary combustion tubing. Now, when we consider that the contents of at least a Winchester quart must have been passed through in order to make the necessary estimations, it will be at once apparent that the

for analysis twice through the coke in about 18 hours. In the majority of our recorded experiments, we had, therefore, a filtering depth of about 58 inches. The coke was thoroughly washed, and many litres of water were passed through before a sample was collected for examination. We found that, within limits, no material alteration was effected by varying the rate of filtration. After the filter was once started, the surface of the coke was never allowed to become exposed to the air. Table A below gives some of the results we have obtained in this way.

It will at once be seen that these results in no way accord with those obtained by Dr. Percy Frankland upon the miniature scale. On the contrary, they

* Grossly polluted samples.

amount of surface exposed to such a relatively large bulk of water was far too small to allow of any accurate idea being formed as to whether any chemical purification was to be effected by constituting coke as the filtering medium. Experiments which one of us had made upon the industrial scale had fully convinced us that coke did effect a very marked chemical purification, and we decided, therefore, to submit it to some laboratory test of an accurate character. We took some good samples of ordinary gas-coke, and powdered them up till they were finely divided. The powder was then introduced into a glass tube 2½ inches wide, and of such a length that we were enabled to have a filtering depth of coke of 29 inches. We allowed the water under examination to pass through this at such a rate that we were enabled to filter the Winchester quart required

show that a most marked chemical purification is effected; in some cases, indeed, quite as emphatic as with spongy iron. This being so, we can fully understand why Dr. Percy Frankland should have found that coke is so strongly germicidal; and we venture to think that if he repeat his experiments upon a scale approaching to ours, he will be the first to confirm the figures we have quoted.

We would here remark, that caution is in all cases necessary before deciding as to whether a sterilisation of water is produced by a purely mechanical filtration. In support of our view, we may instance the beautiful sand found in the bed of one of the Scotch lakes. It was supposed to be extremely pure in every respect, but notwithstanding has been found to be a veritable necropolis of diatoms; and we may further quote some experiments of our own, undertaken

during the course of this investigation, in which we sought to make small plates of mica the inert agent upon which to fix a certain purifying material. We submitted the mica to prolonged heat before using it, and found, contrary to our expectations, that the water was much more impure after filtration than before it. On further examination, we proved to demonstration that the organic impurity was derived from the mica, and this notwithstanding that it is supposed to be a pure silicate of magnesium, and that we had taken the precaution to submit it to the action of prolonged heat before using it. Who shall

weathered it is extremely probable that the iron becomes oxidised, more especially upon the exterior; but if it be used when fresh it will contain metallic iron in relatively considerable quantity. This may be proved by the possibility of collecting hydrogen gas when acting upon coke with acids. Hence, if such coke be powdered so that the interior of the lumps can be thoroughly mixed with the rest of the mass, we have the conditions which we have stated to be favourable to chemical purification—viz., two dissimilar bodies in intimate mechanical contact, one of which is easily susceptible of oxidation. We have,

21st day—						
Before filtration	31.38	.295	.048	0	.273	23.00
After „	30.16	.090	.051	.028	.223	23.30
25th day—						
Before filtration	33.50	.211	.045	0	.265	23.90
After „	30.68	.121	.051	.010	.218	23.60

say, then, that there are not some unknown conditions influencing the sterilising properties of all those filtering bodies at present supposed to act mechanically in producing sterilisation?

And now let us inquire why it is that coke produces so emphatic a chemical purification. We have never yet examined a sample of coke which did not contain iron. In furnace coke its proportion would be more pronounced than in the case of gas coke. When the coke is first made, the iron is probably all in the metallic condition, and is, moreover, in a state of fine division, and in intimate mechanical contact with the carbon, which has reduced it. If it be much
